the above nonmonotone line search. Surprisingly, a variant of the DYCD method tested in Dai [14] was able to solve all the 18 test problems in Moré *et al* [68].

SUFFICIENT DESCENT CONJUGATE GRADIENT METHODS

In this section, we summarize several nonlinear conjugate gradient methods that can guarantee the sufficient descent condition (10), especially the CG_Descent method by Hager and Zhang [7,69].

Though the sufficient descent condition (10) is not scale invariant, there is, however, some difficulty to differentiate *descent* conjugate gradient methods and *sufficient descent* conjugate gradient methods. More exactly, if d_k satisfies $g_k^T d_k < 0$, we can define another method whose search direction is $\bar{d}_k = (-c \|g_k\|^2 / g_k^T d_k) d_k$, such that $g_k^T \bar{d}_k = -c \|g_k\|^2$.

Let us take the DY method as an illustrative example. A variant of the DY method is given in Dai [55], where d_k takes the form

$$d_k = -\frac{d_{k-1}^T y_{k-1}}{\|g_k\|^2} g_k + d_{k-1}. \quad (95)$$

Since $d_1 = -g_1$, we can get by the induction principle that

$$g_k^T d_k = -\|g_1\|^2, \quad \text{for all } k \geq 1. \quad (96)$$

Further, if a scaling factor $\|g_k\|^2 / \|g_{k-1}\|^2$, that is, the formula β_k^{FR} exactly, is introduced for each search direction d_k (except d_1), we obtain the scheme

$$d_k = -\frac{d_{k-1}^T y_{k-1}}{\|g_{k-1}\|^2} g_k + \beta_k^{\text{FR}} d_{k-1}. \quad (97)$$

In this case, we have that $-g_k^T d_k = \|g_k\|^2$ for all k , which implies that the sufficient descent condition (10) holds with $c = 1$. It is worth mentioning that the above scheme (97) is obtained by Zhang *et al.* [70] (see also the section titled “Several New Methods That Guarantee Sufficient Descent”) with the motivation of modifying the FR method. They

found that, the numerical performance of this scheme is very promising for a large collection of test problems in the CUTER library [71].

The CG_Descent Method

To ensure the sufficient descent condition (10), Hager and Zhang [7] proposed a family of conjugate gradient methods, where

$$\beta_k^{\text{HZ}}(\lambda_k) = \frac{g_k^T y_{k-1}}{d_{k-1}^T y_{k-1}} - \lambda_k \left(\frac{\|y_{k-1}\|^2 g_k^T d_{k-1}}{(d_{k-1}^T y_{k-1})^2} \right), \quad (98)$$

where $\lambda_k \geq \bar{\lambda} > 1/4$ controls the relative weight placed on the conjugacy degree versus the descent degree of the search direction. This family is clearly related to the DL method (67) with

$$t = \lambda_k \frac{\|y_{k-1}\|^2}{s_{k-1}^T y_{k-1}}. \quad (99)$$

To verify the sufficient descent condition for the Hager and Zhang (HZ) method, we have by Equations (3) and (98) that

$$\begin{aligned} g_k^T d_k &= -\|g_k\|^2 + \left(\frac{g_k^T y_{k-1} (g_k^T d_{k-1})}{d_{k-1}^T y_{k-1}} \right) \\ &\quad - \lambda_k \left(\frac{\|y_{k-1}\|^2 (g_k^T d_{k-1})^2}{(d_{k-1}^T y_{k-1})^2} \right). \end{aligned} \quad (100)$$

Now, by applying

$$\begin{aligned} u_k &= \frac{1}{\sqrt{2\lambda_k}} (d_{k-1}^T y_{k-1}) g_k, \\ v_k &= \sqrt{2\lambda_k} (g_k^T d_{k-1}) y_{k-1} \end{aligned} \quad (101)$$

into the inequality

$$u_k^T v_k \leq \frac{1}{2} (\|u_k\|^2 + \|v_k\|^2), \quad (102)$$

we can obtain

$$\begin{aligned} \frac{g_k^T y_{k-1} (g_k^T d_{k-1})}{d_{k-1}^T y_{k-1}} &\leq \frac{1}{4\lambda_k} \|g_k\|^2 \\ &\quad + \lambda_k \left(\frac{\|y_{k-1}\|^2 g_k^T d_{k-1}}{(d_{k-1}^T y_{k-1})^2} \right). \end{aligned} \quad (103)$$

Therefore by Equations (100) and (103), we have that

$$g_k^T d_k \leq -\left(1 - \frac{1}{4\lambda_k}\right) \|g_k\|^2, \quad (104)$$

which with the restriction of λ_k means that the sufficient descent condition (10) holds with $c = 1 - (4\bar{\lambda})^{-1}$.

In order to obtain global convergence for general nonlinear functions, Hager and Zhang truncated their conjugate gradient parameter similar to the PRP⁺ method. More exactly, they suggested to choose

$$\begin{aligned} \beta_k^{\text{HZ}+}(\lambda_k) &= \max \left\{ \beta_k^{\text{HZ}}(\lambda_k), \eta_k \right\}, \\ \eta_k &= \frac{-1}{\|d_{k-1}\|^2 \min \{\eta, \|g_{k-1}\|\}}, \end{aligned} \quad (105)$$

where $\eta > 0$ is a constant. With this truncation, they established the global convergence of the modified method (105) with the standard Wolfe line search for general functions.

Hager and Zhang [69,72] tested the value of $\lambda_k = 2$ for the family with a precisely developed efficient line search. For a large collection of large-scale test problems in the CUTer library [71], the new method, called CG_DESCENT, performs better than both PRP⁺ of Gilbert and Nocedal and L-BFGS of Liu and Nocedal.

More efficient choices of λ_k , however, have been found in Kou and Dai [73] by projecting the scaled memoryless BFGS direction defined in Equations (60) and (63) into the one-dimensional manifold $\{-g_k + \beta d_k : \beta \in R\}$. By taking the scaling factors $\gamma_{k-1} = \frac{s_{k-1}^T y_{k-1}}{\|y_{k-1}\|^2}$ and $\gamma_{k-1} = \frac{\|s_{k-1}\|^2}{s_{k-1}^T y_{k-1}}$, they suggest the uses of $\lambda_k = 2 - \frac{d_{k-1}^T y_{k-1}}{\|d_{k-1}\|^2 \|y_{k-1}\|^2}$ and $\lambda_k = 1$, respectively. A simple and efficient nonmonotone line search criterion is also designed in Kou and Dai [73], that can guarantee the global convergence of the new methods.

Several New Methods That Guarantee Sufficient Descent

The remarkable property of the HZ method (98) that can guarantee the sufficient descent

condition (10) for general functions have attracted several further investigations.

A direct generalization of Equation (98) is given in Yu and Guan [74] (see also Yu *et al.* [75]). They found that, for any β_k of the form

$$\beta_k = \frac{g_k^T v_k}{\Delta_k}, \quad \text{for some } v_k \in R^n \text{ and } \Delta_k \in R, \quad (106)$$

there is a corresponding formula

$$\beta_k^{\text{YG}}(C) = \frac{g_k^T v_k}{\Delta_k} - \frac{C \|v_k\|^2}{\Delta_k^2} g_k^T d_{k-1}, \quad (107)$$

where $C > 1/4$, such that Equation (10) holds with $c = 1 - (4C)^{-1}$. Since almost all of the conjugate gradient parameters can be written into Equation (106), we can obtain various extensions that can guarantee sufficient descent. It is obvious that the HZ formula (98) is corresponding to Equation (107) with the HS formula (55), where $v_k = y_{k-1}$ and $\Delta_k = d_{k-1}^T y_{k-1}$. The extensions of β_k^{FR} , β_k^{PRP} , β_k^{DY} , β_k^{CD} , and β_k^{LS} are also provided in Yu and Guan [74]. A further generalization of this framework on the spectral conjugate gradient method (see Birgin and Martinez [76] or the section titled “Several Topics on Conjugate Gradient Methods”) is given in Yu *et al.* [75].

Another general way of producing sufficient descent conjugate gradient methods is provided in Cheng [77] and Cheng and Liu [78]. Its basic is as follows. For any search direction $-g_k + \beta_k d_{k-1}$, which need not be descent, an orthogonal projection to the null space of g_k leads to the vector

$$d_k^\perp = \left(I - \frac{g_k g_k^T}{\|g_k\|^2} \right) (-g_k + \beta_k d_{k-1}). \quad (108)$$

The search direction defined by

$$\begin{aligned} d_k &= -g_k + d_k^\perp = -\left(1 + \beta_k \frac{g_k^T d_{k-1}}{\|g_k\|^2} \right) \\ &\quad g_k + \beta_k d_{k-1} \end{aligned} \quad (109)$$

then always satisfies $g_k^T d_k = -\|g_k\|^2$. If the line search is exact, the second term in the paranthesis of Equation (109) is missing

since $g_k^T d_{k-1} = 0$. Hence the above scheme reduces to the linear conjugate gradient method in the ideal case. The above procedure with $\beta_k = \beta_k^{\text{PRP}}$ is studied in Cheng [77]. As shown in Cheng and Liu [78], setting $\beta_k = \beta_k^{\text{FR}}$ in Equation (109) leads to the scheme (97). Another variant corresponding to Yabe and Takano [49] (see the end of the section titled “The Hestenes–Stiefel Method”) is also investigated in Cheng and Liu [78].

Observing that the search direction (64) defined by the memoryless BFGS method is formed by the vectors $-g_k$, d_{k-1} , and y_{k-1} , Zhang *et al.* [17] proposed the following modification of the PRP method

$$d_k = -g_k + \frac{g_k^T y_{k-1}}{\|g_{k-1}\|^2} d_{k-1} - \frac{g_k^T d_{k-1}}{\|g_{k-1}\|^2} y_{k-1}. \quad (110)$$

By multiplying the above d_k with g_k^T , one can see that the corresponding values of the last two terms have opposite signs and hence $g_k^T d_k = -\|g_k\|^2$. The above scheme was implemented in Zhang *et al.* [17] with an Armijo-type line search in relation to De Leone *et al.* [40], yielding comparable numerical results with CG_DESCENT. Although Equation (110) reduces to Equation (3) in case of exact line searches, this scheme is not a standard conjugate gradient method of the form (3) any more.

SEVERAL TOPICS ON CONJUGATE GRADIENT METHODS

As shown in the previous sections, various formulas have been proposed for the nonlinear conjugate gradient parameter β_k , whereas there is not much to do with the choice of this parameter in the linear conjugate gradient method (it is a consensus to use the FR formula (31) there). While some of the existing conjugate gradient algorithms, like the DYHS method (87) and the CG_DESCENT method (98) among others, have proved more efficient than the PRP method, we feel there is still much more room to seek the best nonlinear conjugate gradient algorithms.

As a lot of attention has been paid to the choice of β_k , it is actually also important how to choose the stepsize α_k . Some joint consideration is given by Yuan and Stoer [79], which aims to find the best points of the function over the two-dimensional manifold

$$x_k + \text{Span} \left\{ -\alpha g_k + \beta d_{k-1} : \alpha, \beta \in \mathbb{R}^2 \right\} \quad (111)$$

as the next iterates. Motivated by the success of the Barzilai–Borwein stepsize in the steepest descent method [80,81], Birgin and Martinez [76] proposed the so-called spectral conjugate gradient method that takes the search direction

$$d_k = -\frac{1}{\delta_k} g_k + \frac{g_k^T (y_{k-1} - \delta_k s_{k-1})}{\delta_k d_{k-1}^T y_{k-1}} d_{k-1}. \quad (112)$$

The efficient combination of the Barzilai–Borwein method and the conjugate gradient method, however, is still not known to us. Specifically, the study of Dai and Liao [48] indicates that when the iterate gets close to the solution, the Barzilai–Borwein stepsize can always be accepted by the often-employed nonmonotone line search. We wonder whether there is a similar result for the spectral conjugate gradient method or some of its suitable alternatives.

In addition to the standard conjugate gradient methods of the form (2) and (3), another class of two-term conjugate gradient methods is called *method of shortest residuals* (SR), that was first presented by Hestenes [82] and studied by Pytlak and Tarnawski [83], Dai and Yuan [84], and the references therein. The SR method defines the search direction by

$$d_k = -Nr\{g_k, -\beta_k d_{k-1}\}, \quad (113)$$

where β_k is a scalar and $Nr\{a, b\}$ is defined as the point from a line segment spanned by the vectors a and b which has the smallest

norm, namely,

$$\|Nr\{a, b\}\| = \min \{ \|\lambda a + (1 - \lambda)b\| : 0 \leq \lambda \leq 1 \}. \quad (114)$$

If $\beta_k \equiv 1$, the corresponding variant of the SR method generates the same iterations as the FR method does in case of exact line searches. The formula of β_k corresponding to the PRP method is also given in Pytlak [85] and modified in Dai and Yuan [84]. If, further, the function is quadratic, these variants of the SR method are equivalent and the direction d_k proves to be the SR in the $(k - 1)$ -simplex whose vertices are $-g_1, \dots, -g_k$. For the SR method, the descent property of d_k is naturally implied by its definition (see Pytlak [85] and Dai and Yuan [84] for details). In contrast to the standard conjugate gradient method, where the size of d_k may become very large, the SR method has the trend of pushing $\|d_k\|$ very small. Therefore, we wonder whether there exists some family of methods that includes the standard conjugate gradient method and the SR method as its members. If this is the case, it might be possible to find more efficient methods that monitor the size of $\|d_k\|$ in a more efficient way.

If the storage of more vectors is admissible, one may consider to choose, for example, three-term conjugate gradient methods [17,18,86] and limited-memory quasi-Newton methods [87,88] for solving large-scale optimization problems, other than the two-term conjugate gradient methods. As an alternative, one may think of forming some preconditioner for conjugate gradient methods through the information already achieved in the previous fewer iterations [89–91]. Unlike the linear conjugate gradient method, where a constant preconditioner is usually satisfactory, a robust and efficient conjugate gradient method for highly nonlinear functions requires to be dynamically preconditioned. Therefore, it remains to study how to precondition the nonlinear conjugate gradient method in more effective ways.

NONLINEAR MULTIOBJECTIVE PROGRAMMING

ALEXANDER ENGAU

Department of Mathematical and
Statistical Sciences,
University of Colorado Denver,
Denver, Colorado

Multiojective programming is the field within mathematical programming that deals with the simultaneous optimization (maximization or minimization) of a finite number of two or more real-valued objective functions $f_i : \mathbb{R}^n \rightarrow \mathbb{R}$ ($i = 1, 2, \dots, p$) subject to a finite number of real-valued equality or inequality constraints $g_j : \mathbb{R}^n \rightarrow \mathbb{R}$ ($j = 1, 2, \dots, m$). The extension to more general vector spaces or an infinite number of objectives or constraints gives a more general vector optimization problem (VOP), but in this treatment we explicitly consider only the finite-dimensional Euclidean case. Hence, without loss of generality, we now assume that all objectives are to be minimized (otherwise replace $\max f_i(x)$ by $-\min -f_i(x)$) and that all constraints have the form of less-than-or-equal-to inequalities (otherwise replace $g_j(x) = 0$ by $g_j(x) \leq 0$ and $g_j(x) \geq 0$, and $g_j(x) \geq 0$ by $-g_j(x) \leq 0$). With these assumptions, we define the multiojective program (MOP)

MOP: Minimize

$$f(x) := (f_1(x), f_2(x), \dots, f_p(x))^T$$

subject to

$$g(x) := (g_1(x), g_2(x), \dots, g_m(x))^T \leq 0,$$

where $f : \mathbb{R}^n \rightarrow \mathbb{R}^p$ and $g : \mathbb{R}^n \rightarrow \mathbb{R}^m$ are the vector functions comprised of objectives and constraints, respectively, and $x = (x_1, x_2, \dots, x_n)^T \in \mathbb{R}^n$ is the vector of optimization or decision variables. Given MOP, the sets $S := \{x \in \mathbb{R}^n : g(x) \leq 0\}$ and $F := f[S] := \{y \in \mathbb{R}^p : y = f(x) \text{ for some } x \in S\}$ are called the feasible region or set of feasible points, and the set of attainable outcomes, respectively. As in the excluded special case $p = 1$, in

which the above formulation reduces to a single-objective program (SOP), MOP is said to be linear if all functions f_i and g_j are affine (linear plus a constant); combinatorial or (mixed-)integer if all (or some) components of the decision vector x have to be integers; and, respectively, nonlinear and continuous otherwise. Other classifications also distinguish deterministic MOPs from problems under uncertainty in which f and g involve random, stochastic, or fuzzy parameters, and single-level from multilevel problems in which several optimization problems are nested in some hierarchical fashion. Because the resulting additional challenges are often similar to those for SOPs, which are addressed in more detail elsewhere in this encyclopedia, this discussion focuses primarily on deterministic, continuous, nonlinear multiojective programming with the goal of highlighting some of the similarities and differences in the theory and methodology of solving MOPs in contrast to problems with only a single objective. Readers interested in a more comprehensive presentation are directed to the excellent monographs by Ehrgott [1] who offers a well-written introduction to nonlinear, linear, and combinatorial multicriteria optimization both with motivational examples and illustrations as well as numerous exercises; Jahn [2] who gives a rigorous exposition of the theory of more general vector optimization in the setting of partially ordered linear spaces together with many interesting applications in the mathematical and engineering sciences; and Miettinen [3] who provides a balanced treatment of the theory and numerous methods of nonlinear multiojective optimization with a particular focus on interactive procedures and decision making. In addition, in the last few years several bibliographic state-of-the-art surveys on multiojective programming have been written by Ehrgott and Wiecek [4] for an extensive volume on multiple criteria decision analysis [5], and more specifically on nonlinear MOPs [6], combinatorial MOPs [7],

fuzzy and multilevel MOPs [8–10], vector optimization [11], interactive procedures [12,13], and evolutionary algorithms [14–17] for an edited volume on multiple criteria optimization [18]. Finally, some case studies and practical applications in engineering and the sciences are collected in the books by Collette and Siarry [19], Stadler [20], and Wierzbicki *et al.* [21], and a lot of interesting and still relevant material can also be found in the classical but older texts by Chankong and Haimes [22], Cohon [23], Göpfert and Nehse [24], Hwang and Masud [25], Jahn [26], Luc [27], Sawaragi *et al.* [28], Steuer [29], White [30], Yu [31], Zeleny [32], and others. Much narrower in scope than many of these texts that treat the field of multiobjective programming together with the more general discipline of multicriteria decision making (MCDM), however, here we adopt the conceptual distinction between multiobjective programming as mathematical solution of MOPs, which forms the subject of this article, and MCDM as the preferential solution of multicriteria decision problems by one or multiple decision makers, which is discussed by numerous other authors in this encyclopedia. Consequently, this article restricts its focus to several solution concepts for MOPs in the first section, their characterization using optimality conditions and duality in the second section, and some representative generating methods in the third section, all of which are discussed independent of preferential input by a decision maker. Some concluding remarks are offered in the fourth section that is followed by a long list of supplemental references.

SOLUTION CONCEPTS

The fundamental concepts of Pareto optimality, cone efficiency, and nondominance that are reviewed in the section titled “Pareto Optimality, Efficiency, and Nondominance” can be found in essentially any of the above references on multiobjective programming or multicriteria optimization. The subsequent discussion in the section titled “Approximate, Epsilon and Proper Efficiency” describes,

first, approximate (epsilon-)efficiency as a further generalization of these classical concepts and, second, two concepts of proper efficiency with a particular focus on their relationships to trade-offs and trade-off rates.

Pareto Optimality, Efficiency, and Nondominance

Let us first consider the set $F = \{f(x) \in \mathbb{R}^p : g(x) \leq 0, x \in \mathbb{R}^n\}$, where f and g are the objectives and constraints of a deterministic, continuous, nonlinear or linear MOP. Different than for SOPs for which the corresponding sets are sets of real numbers with a well-defined minimum or infimum, F is a set of real vectors with no canonical order to determine an obvious meaning of minimum or minimization. In consequence, a variety of different (partial) orders can be used to compare two vectors or outcomes $f(x)$ and $f(x')$, among which the following three are of relevance for our general discussion in this section or some specific scalarization methods discussed later in the sections titled “Objective Aggregation and Prioritization” and “Reference Points and Norm Minimization”.

- Componentwise (Pareto) orders [33,34]

$$\begin{aligned} f(x) \leq f(x') &: \Leftrightarrow f_i(x) \leq f_i(x') \\ &\text{for all } i = 1, \dots, p, \\ f(x) \preceq f(x') &: \Leftrightarrow f(x) \leq f(x') \\ &\text{and } f(x) \neq f(x'), \\ f(x) < f(x') &: \Leftrightarrow f_i(x) < f_i(x') \\ &\text{for all } i = 1, \dots, p; \end{aligned}$$

- Lexicographic order [35–37]

$$\begin{aligned} f(x) \preceq_{\text{lex}} f(x') &: \Leftrightarrow \\ &f_k(x) < f_k(x') \text{ for some } k = 1, \dots, p, \\ &f_i(x) = f_i(x') \text{ for all } i = 1, \dots, k-1; \end{aligned}$$

- Max orders

$$\begin{aligned} f(x) \leq_{\max} f(x') &: \Leftrightarrow \max_i \{f_i(x)\} \leq \max_i \{f_i(x')\}, \\ f(x) <_{\max} f(x') &: \Leftrightarrow \max_i \{f_i(x)\} < \max_i \{f_i(x')\}. \end{aligned}$$

Pareto Optimality and Efficiency. While the lexicographic order $\leq_{\text{lex}}$ is a total order of $\mathbb{R}^p$ and therefore defines a unique lexicographic minimum in F , if one exists, the component-wise and max orders are only (strict) partial orders and accordingly may only identify a set of incomparable (weak) Pareto minima and min-max solutions, respectively. More precisely, a point $x^* \in S$ and its outcome $y^* = f(x^*) \in F$ are said to be Pareto optimal or weakly Pareto optimal for MOP if there is no other $x \in S \setminus \{x^*\}$ such that $f(x) \leq f(x^*)$ or $f(x) < f(x^*)$, respectively. More generally, if $\preceq$ and $<$ are any partial and associated strict partial orders of $\mathbb{R}^p$, then $x^* \in S$ is said to be efficient or weakly efficient for MOP with respect to $\preceq$ if there is no other $x \in S \setminus \{x^*\}$ such that $f(x) \preceq f(x^*)$ or $f(x) < f(x^*)$, respectively, and its associated outcome $y^* = f(x^*) \in F$ is said to be (weakly) nondominated. Equivalently, based on a definition by Yu [31,38,39], for every $y \in F$ we can define the two domination sets $D(y) := \{d \in \mathbb{R}^p : y \preceq y + d\}$ and $D_w(y) := \{d \in \mathbb{R}^p : y < y + d\}$ and then characterize the sets of efficient and weakly efficient points in S under f with respect to D by

$$E(S, f, D) := \{x^* \in S : \text{there is no}$$

$$y \in F \setminus \{f(x^*)\} \text{ such that } f(x^*) \in y + D(y)\}$$

and $E_w(S, f, D) := E(S, f, D_w)$, respectively, where $y + D := \{y\} + D := \{y + d \in \mathbb{R}^p : d \in D\}$ is defined as the set-algebraic Minkowski sum of the sets $\{y\}$ and D . The corresponding outcome set

$$N(F, D) := \{y^* \in F : \text{there is no } y \in F \setminus \{y^*\} \text{ such that } y^* \in y + D(y)\} = f[E(S, f, D)]$$

and $N_w(F, D) := N(F, D_w)$ of (weakly) nondominated points in F is also called the (weakly) efficient frontier for MOP. In the frequent case that all $D(y)$ are equal, the domination structure D is said to be constant and variable otherwise. In both theory and practice, the most common domination sets are constant pointed convex cones, that is, cones $C \subseteq \mathbb{R}^p$ that satisfy $C \cap (-C \setminus \{0\}) = \emptyset$ and $C + C \subseteq C$. In fact, for every pointed convex cone C with nonempty interior, $\text{int } C \neq \emptyset$, the

associated cone relations $y \preceq_C z : \Leftrightarrow z - y \in C$ and $y <_C z : \Leftrightarrow z - y \in \text{int } C$ determine (strict) partial orders, and conversely, $D(y)$ and $D_w(y)$ are respectively closed and open pointed convex cones if the underlying partial orders are additive and compatible with positive scalar multiplication. The two cones corresponding to the Pareto orders are the nonnegative and positive orthant $\mathbb{R}_{\geq}^p$ and $\mathbb{R}_{>}^p$, which in this context are also called the Pareto cones, and the sets $E(S, f, \mathbb{R}_{\geq}^p)$ and $N(F, \mathbb{R}_{\geq}^p)$ are also known as the Pareto set and alternatively as Pareto frontier, surface, or curve, respectively.

Properties of the Efficient and Nondominated Sets. Primarily focusing on closed convex domination cones, several properties of the efficient and nondominated sets have been investigated including their existence [40–65], structure (boundedness, connectedness, and compactness) [66–99], and stability [100–122,124,125]. An excellent account of these topics and seminal for much of their development with respect to general cones is the monograph by Sawaragi *et al.* [28]. Some specific results can be derived for polyhedral cones, that is, cones $C = \{d \in \mathbb{R}^p : Ad \geq 0\}$ with some matrix $A \in \mathbb{R}^{q \times p}$ that satisfy the well-known relationship $A[N(F, C)] \subseteq N(A[F], \mathbb{R}_{\geq}^q)$ between nondominated points with respect to C in F and Pareto points in $A[F] := \{z \in \mathbb{R}^q : z = Ay \text{ for some } y \in F\}$ with equality if C is pointed, or equivalently, if A has full column rank [28,31,126–130]. Because the underlying efficient sets are then identical, this result provides a useful technique to extend properties or generating methods for the Pareto set to efficient sets with respect to polyhedral cones, or in a generalized form to convex nonpolyhedral cones [131,132]. More general domination sets that are not necessarily convex cones have also been studied by several researchers for both MOP and VOP [31,38,131–144], and variable domination structures have been investigated in the context of vector-variational inequalities in equilibrium problems [145,146] and for modeling variable preferences in economics and decision analysis [147].

Approximate, Epsilon, and Proper Efficiency

Several other notions generalize or further refine the above concepts of Pareto optimality and cone efficiency to various types of approximate or epsilon efficiency [148–150] and proper efficiency.

Approximate and Epsilon Efficiency. Similar to the above definition, now let $D(y) = C$ be a pointed convex cone. For any vector $\varepsilon \in C$, the sets of (weakly) ε -efficient points can be defined by

$$E(S, f, C, \varepsilon) := \{x^* \in S : \text{there is no } y \in F \setminus \{f(x^*)\} \text{ such that } f(x^*) \in y + C + \varepsilon\}$$

and $E_w(S, f, C, \varepsilon) := E(S, f, \text{int } C, \varepsilon)$, respectively. The set $C_\varepsilon := C + \varepsilon$ with $\text{int } C_\varepsilon = \text{int } C + \varepsilon$ is a translated cone that satisfies $E(S, f, C_\varepsilon) = E(S, f, C, \varepsilon)$ and $E_w(S, f, C_\varepsilon) = E_w(S, f, C, \varepsilon)$, and similarly $N(F, C, \varepsilon) = N(F, C_\varepsilon)$ and $N_w(F, C, \varepsilon) = N_w(F, C_\varepsilon)$ for the corresponding (weakly) ε -nondominated sets. In particular, if C is a polyhedral cone with matrix $A \in \mathbb{R}^{q \times p}$, then similar to the result in the section titled “Pareto Optimality, Efficiency, and Nondominance” it follows that $A[N(F, C, \varepsilon)] \subseteq N(A[F], \mathbb{R}_{\geq b}^q)$, where $b = A\varepsilon$ and $\mathbb{R}_{\geq b}^q := \{z \in \mathbb{R}^q : z \geq b\}$ with equality if C is pointed, so that ε -nondominated points in F correspond to ε -Pareto points in the mapped space $A[F]$ [151,152]. Clearly, these results and the above definition reduce to the former if $\varepsilon = 0$, and to the Pareto case if $C = \mathbb{R}_{\geq}^p$ is the Pareto cone. Several other properties of approximate solutions and related concepts have been studied [153–185]. Not only of interest for various theoretical and computational reasons, the independent relevance of approximate solutions has also been highlighted in several practical applications for minimum-cost flows [186], finance [187], transportation [188], location [189], scheduling [190], engineering design [191,192], and decomposition techniques [193,194]. Finally, if $F \subseteq \mathbb{R}_{\geq}^p$, $C = \mathbb{R}_{\geq}^p$, and $0 \leq \varepsilon \leq 1$ is a real number, then an alternative multiplicative definition of approximate efficiency calls a point $x^* \in S$ ε -efficient if there is no other $x \in S \setminus \{x^*\}$ such that $f(x) \leq (1 - \varepsilon)f(x^*)$, which also has been used for the approximation of trade-offs [195].

Trade-Offs and Proper Efficiency. In general, a (point-to-point) trade-off between two feasible points x^1 and x^2 in S , with respect to two objectives f_i and f_j with $f_j(x^1) - f_j(x^2) \neq 0$, is defined by the ratio $(f_i(x^2) - f_i(x^1))/(f_j(x^1) - f_j(x^2))$ [22], and under suitable differentiability properties of f , the trade-off rate at a single point $x \in S$ with respect to f_i and f_j can be defined by $\partial f_i(x)/\partial f_j$. On the basis of these concepts, a Pareto optimal point $x^* \in S$ is said to be properly efficient in the sense of Geoffrion [196] or, if both f and g are continuously differentiable, in the sense of Kuhn and Tucker (KT) [197] if all trade-offs are bounded, that is, if there exists some positive number $M > 0$ such that

$$(f_i(x^*) - f_i(x))/(f_j(x) - f_j(x^*)) \leq M$$

for some j such that $f_j(x^*) < f_j(x)$,

whenever $f_i(x) < f_i(x^*)$ for some i and $x \in S$, or if there is no $h \in \mathbb{R}^n$ such that $\nabla f(x)h < 0$ and $\nabla g_j(x)h \leq 0$ whenever $g_j(x) = 0$, respectively. In particular, if all f_i and g_j are convex, then proper efficiency in the sense of KT implies proper efficiency in the sense of Geoffrion, and the reverse is true under an appropriate Kuhn–Tucker constraint qualification (KTCQ), for example, if for any $d \in \mathbb{R}^n$ such that $\nabla g_j(x)d \leq 0$ and $g_j(x) = 0$, there exists a differentiable function $h(t)$ and real numbers $(\alpha, T) > 0$ such that $h(0) = x$, $\dot{h}(0) = \alpha d$, and $g(h(t)) \leq 0$ for all $t \in [0, T]$ [3]. The above definitions of trade-offs have been extended to trade-offs along feasible directions [198–201] and other, more general trade-off directions based on the concepts of normal, polar, and tangent cones [202–206]. Many other properties as well as further generalizations to superefficiency [207,208] and other notions of proper efficiency with respect to cones have been investigated by Benson [209,210], Borwein [211], Corley [212], Hartley [76], Henig [213,214] and numerous other scholars [204,215–265]. Characterizations and connections between many of the different definitions of proper efficiency are collected by Sawaragi *et al.* [28]. In particular, if we denote the set of properly efficient points by $E_p(S, f, C)$ and choose $\varepsilon \in \text{int } C$ in the definition of epsilon

efficiency, then in each case one of the most general characterizations is the set inclusion

$$\begin{aligned} E_p(S, f, C) &\subseteq E(S, f, C) \subseteq E_w(S, f, C) \\ &\subseteq E(S, f, C, \varepsilon) \subseteq E_w(S, f, C, \varepsilon). \end{aligned}$$

OPTIMALITY CONDITIONS AND DUALITY

Classical nonlinear programs are typically solved using iterative methods applied to an associated system of nonlinear equations based on some set of optimality conditions or, alternatively, a dual or primal–dual penalty or barrier (interior-point) formulation. For MOP, similar optimality conditions and duality results have been derived for both Pareto optimality and cone efficiency, and are briefly reviewed in the sections titled “First- and Second-Order Conditions for Pareto Optimality” and “Duality and Sensitivity Analysis” based on presentations by Miettinen [3] and Tanino and Kuk [6].

First- and Second-Order Conditions for Pareto Optimality

The following conditions for MOP are very similar to those derived for SOP in terms of the Lagrangian function. To highlight this similarity, we restrict our discussion to the Pareto case; the extension to general cones is straightforward and merely requires an appropriate choice of multipliers from the respective dual cones as mentioned in some more detail at the end of the section.

First-Order Conditions. First, let f_i and g_j be continuously differentiable at a (weakly) Pareto optimal point $x^* \in S$. The multiobjective version of the Fritz–John (FJ) necessary conditions [266] state that then there exist two nonnegative vectors $\mu \in \mathbb{R}_{\geq}^p$ and $\lambda \in \mathbb{R}_{\geq}^m$ that satisfy $(\mu, \lambda) \succeq 0$ and

$$\begin{aligned} \sum_{i=1}^p \mu_i \nabla f_i(x^*) + \sum_{j=1}^m \lambda_j \nabla g_j(x^*) &= 0, \\ \lambda_j g_j(x^*) &= 0 \text{ for all } j = 1, \dots, m. \end{aligned}$$

More specifically, the multiobjective version of the KT conditions [197] states that the

same conditions hold with $\mu \succeq 0$ if x^* either satisfies the KT constraint qualification (KTCQ) from the section titled “Approximate, Epsilon and Proper Efficiency” or is regular, that is, the gradient vectors $\nabla g_j(x^*)$ of all active constraints $g_j(x^*) = 0$ are linear independent [267]. Furthermore, if all f_i and g_j are convex, or more generally, if all f_i are pseudoconvex and g_j quasiconvex, then these conditions are also sufficient for a (weakly) Pareto optimal point if μ can be chosen (strictly) positive and nonzero [3, 268–270]. Finally, if x^* is properly efficient (in the sense of KT), then μ can be chosen strictly positive and λ nonnegative, and these conditions are also sufficient if f_i and g_j are convex. While the FJ conditions were originally given for SOPs, the KT conditions were also prepared for multiple objectives in the seminal paper by Kuhn and Tucker [197] and similarly apply for proper efficiency in the sense of Geoffrion if x^* satisfies the KTCQ or one of several alternative regularity or constraint qualifications [271–276]. In particular, if f_i and g_j are locally Lipschitz but not necessarily continuously differentiable, then extensions of the above conditions remain true under appropriate constraint qualifications [3] if the gradients in the first condition are replaced by subdifferentials, so that 0 must only be contained in the corresponding set of subgradient vectors

$$0 \in \sum_{i=1}^p \mu_i \partial f_i(x^*) + \sum_{j=1}^m \lambda_j \partial g_j(x^*).$$

Second-Order Conditions. If f_i and g_j are twice continuously differentiable at a regular (weakly) Pareto optimal point $x^* \in S$, then the above conditions remain satisfied for $\mu \succeq 0$ and $\lambda \geq 0$, and

$$d^T \left(\sum_{i=1}^p \mu_i \nabla^2 f_i(x^*) + \sum_{j=1}^k \lambda_j \nabla^2 g_j(x^*) \right) d \geq 0,$$

for all $d \in \mathbb{R}^n$ such that $\nabla f_i(x^*)d \leq 0$ for all $i = 1, \dots, p$, and $\nabla g_j(x^*)d = 0$ whenever $g_j(x^*) = 0$. These conditions are also sufficient if the above inequality holds strictly for either all d such that $\nabla f_i(x^*)d \leq 0$ for

all $i = 1, \dots, p$ and $\nabla g_i(x^*)d \leq 0$ whenever $g_i(x^*) = 0$, or alternatively, for all d such that $\nabla g_i(x^*)d \leq 0$ whenever $g_i(x^*) = 0$ with equality if $\lambda_i > 0$ [3,277]. A large number of papers have extended the above results or proposed new first- and second-order conditions for Pareto optimality or efficiency with respect to general cones [277–355]. In particular, the results given above remain valid for weakly or properly efficient points with respect to a convex cone $C \subseteq \mathbb{R}^p$, if the choice of constraint multipliers μ is restricted to elements from one of the two respective dual cones $C_{\geq}^+ := \{\mu \in \mathbb{R}^p : \mu^T d \geq 0 \text{ for all } d \in C\}$ and $C_{>}^+ := \{\mu \in \mathbb{R}^p : \mu^T d > 0 \text{ for all } d \in C \setminus \{0\}\}$.

Duality and Sensitivity Analysis

Two other large parts of the literature deal with duality theory and different types of dual problems as well as the related topics of sensitivity analysis and stability already mentioned in the section titled “Pareto Optimality, Efficiency, and Nondominance”. Dependent on more advanced topics in set-valued optimization, therefore, we limit this only very brief introduction to the set-valued Lagrangian dual problem and the set-valued perturbation map.

Lagrangian Duality. Similar to the Lagrangian function in nonlinear programming, for MOP we can introduce a vector-valued Lagrangian function $L(x, \Lambda) := f(x) + \Lambda g(x)$ where $\Lambda \in \mathbb{R}^{p \times m}$ is a matrix that preserves nonnegativity, that is, $\Lambda d \geq 0$ whenever $d \geq 0$. In further extension of the Lagrangian dual problem, we define a set-valued dual map $\Phi(\Lambda) := N(L[S, \Lambda], \mathbb{R}_{\geq}^p)$ where $L[S, \Lambda] := \{L(x, \Lambda) \in \mathbb{R}^p : x \in S\}$ and consider the associated set-valued optimization problem

$$\begin{aligned} &\text{Maximize } \phi(\Lambda) \\ &\text{subject to } \Lambda \in \mathcal{L} := \{\Lambda \in \mathbb{R}^{m \times k} : \Lambda d \geq 0 \\ &\quad \text{for all } d \geq 0\} \end{aligned}$$

as the dual problem for MOP. Although the optimal solution sets for the original MOP and the above dual problem do not coincide, in general, several other properties between these two sets, and these two sets

of problems in general have been derived [6,28]. A more detailed discussion of this and other concepts of duality, including conjugate and axiomatic types, are given in the earlier surveys by Tanino and Kuk [6], Tammer and Göpfert [11], and a large number of other older and newer papers [258,356–496].

Sensitivity Analysis. Like in linear and nonlinear programming, sensitivity in MOP refers to the effects of changes in the problem data onto the set of optimal solutions, here, specifically the set of nondominated points. Hence, if we consider the parametrized MOP with parameter u (MOP(u))

$$\begin{aligned} &\text{MOP}(u): \text{Minimize} \\ &f(x, u) := (f_1(x, u), f_2(x, u), \dots, f_p(x, u))^T \\ &\text{subject to} \\ &g(x, u) := (g_1(x, u), g_2(x, u), \dots, g_m(x, u))^T \leq 0, \end{aligned}$$

then we can also define the associated sets of (weakly, properly) nondominated points with respect to u resulting in the set-valued maps $N(u) := N(F(u), D)$, $N_w(u) := N_w(F(u), D)$, and $N_p(u) := N_p(F(u), D)$ where $F(u) := \{f(x, u) \in \mathbb{R}^p : g(x, u) \leq 0\}$. The investigation of stability and sensitivity of MOP then pertains to the study of the continuity properties of the perturbation maps $N(u)$, $N_w(u)$, and $N_p(u)$ as well as their contingent derivatives, respectively. Precise definitions with more details and further references are provided in Gal and Wolf [110], and again in the annotated survey by Tanino and Kuk [6] as well as several other older and newer papers [123,497–517].

SCALARIZATION AND GENERATING METHODS

A great variety of solution methods exists for generating efficient solutions and nondominated points, which typically use or combine objective aggregations by a weighted sum, objective prioritization by constraining techniques and hierarchical orders, or some form of norm or distance minimization to some reference point [1–4]. The common characteristic of all these methods is that the original MOP is replaced by a parametrized

single-objective program (SOP) whose real-valued objective function $s : \mathbb{R}^p \rightarrow \mathbb{R}^1$ is (strictly) increasing with respect to the underlying order or ordering cone C , that is, $s(f(x)) \leq s(f(x'))$ or $s(f(x)) < s(f(x'))$ whenever $f(x') \in f(x) + C$ or $f(x') \in f(x) + \text{int } C$ ($f(x') \in f(x) + C \setminus \{0\}$), respectively. In this case, if x^* is an optimal solution for the parametrized problem (SOP(π))

$$\begin{aligned} \text{SOP}(\pi) : \text{Minimize } (s \circ f)(x) &:= s(f(x)) \\ \text{subject to } x &\in S, \end{aligned}$$

for some suitable scalarization parameter π , then x^* is a weakly efficient or efficient point for MOP if the scalarization function s is increasing or strictly increasing, respectively. Of particular interest are those functions s that can find any efficient solution (called completeness by Wierzbicki [518]) and produce only efficient solutions (“constructiveness”), or equivalently, that fully separate nondominated points from dominated points with variation of the scalarization parameters. General conditions for the existence and characterizations of such separating functions have been studied by Wierzbicki [518] and Gerth and Weidner [519].

Objective Aggregation and Prioritization

We begin this brief overview of solutions approaches with the two most popular scalarization methods.

Weighted-Sum Method. The arguably most common method to generate efficient solutions in practice in spite of its well-documented limitations [3, 29, 520–522] combines all objective functions in the form of a nonnegative linear combination or weighted sum [196, 523–527]

$$\begin{aligned} \text{WS}(w) : \text{Minimize } \sum_{i=1}^p w_i f_i(x) \\ \text{subject to } x &\in S, \end{aligned}$$

where the nonzero weighting vector w is chosen to be nonnegative or, more generally, from the dual cone $C_{\geq}^+ = \{w \in \mathbb{R}^p : w^T d \geq 0 \text{ for all } d \in C\}$ for the generation of Pareto

optimal points or efficient solutions with respect to C , respectively. In particular, an optimal solution for $\text{WS}(w)$ is weakly or properly efficient if w belongs to C^+ or $\text{int } C^+$, respectively, and any efficient point can be generated if MOP is convex, that is, if all objectives f_i and constraints g_j are convex functions so that both F and S are convex sets, or more generally, if F is C -convex, that is, if $F + C$ is convex. These restrictions (that unfortunately are often ignored in practice) follow from the geometric interpretation of w as the normal vector of a supporting hyperplane of F that exists at any boundary point $z \in F$ or $z \in N(F, C)$ if and only if F is convex or C -convex, respectively. Furthermore, if f is continuously differentiable at an optimal solution x^* of $\text{WS}(w)$ and provided that $w_i \neq 0$, then the weights satisfy

$$\partial f_i(x) / \partial f_j|_{x=x^*} = -w_j / w_i$$

and also give information about the trade-off rates between f_i and f_j at this solution [528, 529]. The weighted-sum method for Pareto points has been extended by additional constraints [530–532]

$$\begin{aligned} \text{WS}(w, b) : \text{Minimize } \sum_{i=1}^p w_i f_i(x) \\ \text{subject to } f(x) &\leq b \text{ and } x \in S, \end{aligned}$$

which can be generalized for arbitrary ordering cones by replacing the componentwise inequality constraint by the cone constraint $b - f(x) \in C$. While the results on generating (weakly) efficient solutions remain unchanged compared to $\text{WS}(w)$, now every efficient point $x^* \in S$ can be generated as the optimal solution for $b = f(x^*)$ without convexity assumption on f, g, S , or F . In particular, for $C = \mathbb{R}_{\geq}^p$ and $w = e := (1, \dots, 1)^T \in \mathbb{R}^p$, this modified method is equivalent to Benson’s method [42] that is often used to either generate solutions or to confirm Pareto optimality of some given point similar to one of several other direction-based approaches for general pointed convex cones [533–535]. Finally, another important special case

follows when $w = e_k$ is the k th-unit vector

$$\begin{aligned} \text{WS}(e_k, b) : \text{Minimize } & f_k(x) \\ \text{subject to } & f(x) \leq b \text{ and } x \in S, \end{aligned}$$

which is equivalent to the frequently used epsilon-constraint method (that we will therefore discuss separately) if we set $b_i = \varepsilon_i$ for all $i \neq k$ and $b_k \geq \sup\{f_k(x) : f_i(x) \leq b_i \text{ (} i \neq k \text{), } x \in S\}$ [22,536].

Epsilon-Constraint Method. Together with $\text{WS}(w)$ one of the two most commonly used approaches for generating Pareto points and essentially a special case of $\text{WS}(w, b)$, this method does not aggregate the objective vector but prioritizes a single objective f_k while reformulating all others as new constraints

$$\begin{aligned} \text{EC}_k(\varepsilon) : \text{Minimize } & f_k(x) \\ \text{subject to } & f_i(x) \leq \varepsilon_i \text{ (} i \neq k \text{) and } x \in S. \end{aligned}$$

In this case, a point $x^* \in S$ is weakly Pareto optimal or Pareto optimal for MOP if it solves $\text{EC}_k(\varepsilon)$ for some or all k , respectively, or uniquely for at least one k [22]. In particular, x^* is efficient if and only if x^* is optimal for $\text{CO}_k(f(x^*))$ for all $k = 1, \dots, p$, and several other characterizations [537,538] and modifications of this method have been proposed to also improve the detection of (properly) Pareto optimal points [539]. Furthermore, under the same differentiability assumption as for $\text{WS}(w)$ and now based on the sensitivity theorem from nonlinear programming [540,541], the associated trade-off rates between f_i and f_j at an optimal solution x^* of $\text{CO}_k(b)$ are given by

$$\begin{aligned} \partial f_k(x) / \partial f_i|_{x=x^*} &= -\lambda_{ki}^* \\ \text{for all } i &= 1, \dots, m, i \neq k, \end{aligned}$$

where λ_{ki}^* is the Lagrangian multiplier associated with the constraint $f_i(x^*) \leq b_i$ in $\text{CO}_k(b)$ [22]. Finally, a variation of this method is the multi-level lexicographic approach that solves the series of problems

$$\begin{aligned} \text{LM}_k : \text{Minimize } & f_k(x) \\ \text{subject to } & f_i(x) \leq y_i^* \text{ for all } i = 1, \\ & \dots, k-1 \text{ and } x \in S, \end{aligned}$$

where y_i^* are the optimal objective values from each previous subproblem $\text{LM}_i, i = 1, \dots, k-1$ [1]. Consequently, the final solution x^* of this hierarchical method will satisfy $y^* = f(x^*) \leq_{\text{lex}} f(x)$ for all $f(x) \in F \setminus \{f(x^*)\}$ and thus produce the (unique) lexicographic minimum of F , if it exists.

Reference Points and Norm Minimization

The following approaches are generally known as reference-point or direction-based methods [542] and typically formulated to find efficient points whose outcomes are in some sense closest to the ideal or an utopian point $u \in \mathbb{R}^p$, for which $u_i + \epsilon \leq \inf\{f_i(x) : x \in S\}$ for all $i = 1, \dots, p$ with (ideally) $\epsilon = 0$ or (utopian) $\epsilon > 0$. For numerical or comparability purposes, together with the nadir point $v \in \mathbb{R}^p$ for which $v_i = \sup\{y_i : y \in N(F, \mathbb{R}_{\leq}^p)\}$, ideal or (close) utopian points are also often used to scale or normalize each single objective f_i by $\tilde{f}_i(x) := (f_i(x) - u_i)/(v_i - u_i)$, provided that $u_i < v_i$.

Chebyshev Norm Method. Originating in the approximation of the ideal point in compromise programming [543] solvable using ℓ_p -programming techniques [544], the (weighted) Chebyshev norm method

$$\begin{aligned} \text{CN}(w, u) : \text{Minimize } & \max_{i=1, \dots, p} \{w_i(f_i(x) - u_i)\} \\ \text{subject to } & x \in S \end{aligned}$$

with nonnegative weights $w \geq 0$ is based on the (computationally easily tractable) ℓ_∞ -norm and has been proposed by several researchers [29,219,545] as a generating method for optimal solutions with respect to a weighted (by the weights w_i) and shifted (by the reference-point components u_i) version of the max-order introduced in the section titled “Pareto Optimality, Efficiency, and Nondominance”. In this case, a solution $x^* \in S$ is Pareto optimal for MOP if and only if there exists $w > 0$ such that x^* is optimal for $\text{CN}(w, u)$, and several variants and extensions to guarantee that every optimal solution for $\text{CN}(w, u)$ is also Pareto optimal for MOP have been proposed in the form of augmented Chebyshev norms [29,546] and other modifications [547]. In further

generalization, weighted- ℓ_p norms have been replaced by oblique norms [548–550], and consequences of choosing different locations for the reference point have been investigated [551]. Moreover, if $w = e$ and $u = 0$, then $\text{CN}(e, 0)$ reduces to the max-norm scalarization or max-ordering approach that has also been studied independently [1,552]. Finally, the associated trade-off rates

$$\partial f_i(x)/\partial f_j|_{x=x^*} = -\lambda_j^* w_j / \lambda_i^* w_i$$

can be obtained similar to the epsilon-constraint method by rewriting $\text{CN}(w, u)$ in the equivalent form

$$\begin{aligned} & \text{Minimize } \alpha \\ & \text{subject to } \alpha \geq w_i(f_i(x) - u_i) \text{ for all} \\ & \quad i = 1, \dots, p \text{ and } x \in S \end{aligned}$$

where λ_i^* is again the Lagrangian multiplier associated with each constraint $\alpha \geq w_i(f_i(x^*) - u_i)$, $i = 1, \dots, p$ [553].

Pascoletti–Serafini Method. Similar to the geometric interpretation of the weight vector w as normal vector of a separating hyperplane in the weighted-sum method, the weights w in the Chebyshev norm method can also be associated with a direction vector v using the more general scalarization method proposed by Pascoletti and Serafini [535]. Specifically, if we replace all weights $w_i > 0$ in $\text{CN}(w, u)$ by $v_i := w_i^{-1}$ (otherwise, if $w_i = 0$, we can simply drop objective f_i from the problem) and the componentwise inequality $\alpha v \geq f(x) - u$ by the corresponding cone constraint $u + \alpha v \in f(x) + C$ for some pointed convex cone C , then we obtain the Pascoletti–Serafini method

$$\begin{aligned} & \text{PS}(v, u) : \text{Minimize } \alpha \\ & \text{subject to } u + \alpha v \in f(x) + C \text{ and} \\ & \quad x \in S, \end{aligned}$$

which also extends several other direction-based approaches [533,534]. In particular, if $v = e_k$, $u = \varepsilon$, and $C = \mathbb{R}_{\geq}^p$ is the Pareto cone, then $\text{PS}(e_k, \varepsilon)$ reduces to the epsilon-constraint method $\text{EC}_k(\varepsilon)$ showing that

$\text{PS}(v, u)$ may serve as a generalization for both the epsilon-constraint and Chebyshev norm method for general ordering cones. Its main result states that if $(\alpha^*, x^*) \in \mathbb{R} \times S$ is optimal for $\text{PS}(v, u)$ with $u + \alpha^* v \in f(x^*) + C$, then x^* is weakly efficient for MOP and there exists an efficient solution $x^{**} \in E(S, f, C)$ such that $u + \alpha^* v \in f(x^{**}) + C$. This unifying method has the intuitive geometric interpretation to project the point u in direction of v onto the closest point of F after translation by some arbitrary element of the ordering cone C , is a direct consequence of more general separation results in nonlinear programming [519], and recently has also been used for a new adaptive scalarization method based on additional sensitivity considerations [554–556].

ADDITIONAL TOPICS AND CONCLUDING REMARK

In addition to the necessarily very limited list of concepts and methods selected for this short overview of nonlinear multiobjective programming, more recent research also focuses on other solution approaches that do not rely on scalarization but act directly on a certain set of optimality conditions in resemblance to classical nonlinear programming. Novel work in this interesting area is still ongoing with a particular focus on Newton or steepest descent methods [557–563], proximal methods [564–566], and barrier methods or other primal/dual strategies [567–569]. In addition, the continued theoretical investigation of duality and optimality conditions under particular assumptions clearly provides another unlimited plethora of creative research opportunities although not necessarily with a strong relevance for computations or practical purposes as the underlying assumptions and conditions are very often very difficult to actually verify. From that standpoint, the majority of current efforts in actually solving multicriteria optimization problems other than by using scalarization and standard single-objective programming seems to focus primarily on combinatorial problems and the development of new heuristics or metaheuristics. To conclude, however,

the author offers his humble apology should he have overlooked any other recent (or previous) contribution as well as any possible miscitation, and for inevitably missing many other related references of relevance. Specific suggestions in that regard would be greatly appreciated for future revisions of this article.

Acknowledgment

The author most gratefully thanks his doctoral advisor Margaret M. Wiecek for introducing him to the field of multiobjective programming, and to the editors and an anonymous referee for their insightful comments and helpful suggestions that have lead to the improved presentation of this contribution.

NONSTATIONARY INPUT PROCESSES

MICHAEL E. KUHL
Industrial & Systems Engineering
Department, Rochester Institute of
Technology, Rochester, New York

MODELING AND SIMULATING NONSTATIONARY INPUT PROCESSES

Nonstationary input processes are often encountered in the application of systems simulation. The arrival patterns of customers to a bank, incoming calls to a call center, arrival of patients to a hospital emergency room, demands for seasonal products such as lawn mowers, and the arrival of passengers to an airport are all examples of situations where the arrival rates may change over time. To successfully simulate the operation of these types of systems, it often requires stochastic input process that can accurately mimic the arrival pattern and changes in the arrival rates over time. This article focuses on two methods for representing nonstationary input processes, namely, nonhomogeneous Poisson processes and nonstationary non-Poisson processes.

Nonhomogeneous Poisson processes (NHPPs) have been used successfully to model complex time-dependent arrival processes in a broad range of applications including the arrival of events in a data base system [1], the arrival of storms to an off-shore drilling site [2], and the arrival patterns of organ transplant patients and organ donors in a simulation model used to analyze liver-transplant policies in the United States [3,4]. The behavior of NHPPs includes independence of the number of arrivals in nonoverlapping intervals of time, individual arrivals, and other characteristics that are defined in detail in the next section. Although there is a large class of nonstationary arrival processes that have the characteristics of

NHPPs, there also exists situations where other methods are needed. Research into these processes has been ongoing. In particular, Gerhardt and Nelson [5] have developed methods for modeling and simulating nonstationary non-Poisson arrival processes.

In this article we discuss various methods for modeling and simulating NHPPs as well as nonstationary non-Poisson process with emphasis on their advantages and limitations in practice. The content of this article includes material presented in a series of input modeling tutorials presented at the Winter Simulation Conference [6] as well as from Kuhl and Wilson [7].

NONHOMOGENEOUS POISSON PROCESSES

A nonhomogeneous Poisson process $\{N(t) : t \geq 0\}$ is a generalization of a Poisson process in which the instantaneous arrival rate $\lambda(t)$ at time t is a nonnegative integrable function of time. The mean-value function of the NHPP is defined by

$$\mu(t) \equiv E[N(t)] = \int_0^t \lambda(z) dz \text{ for all } t \geq 0.$$

An NHPP has the following properties [8]:

1. $\{N(t) : t \geq 0\}$ is a counting process;
2. $N(0) = 0$;
3. $\{N(t+s) - N(t) : s \geq 0\}$ is independent of $\{N(u) : 0 \leq u < t\}$ for all $t \geq 0$;
4. $\Pr\{N(t+h) - N(t) = 1\} = \lambda(t)h + o(h)$ for all $t \geq 0$ and $h > 0$; and
5. $\Pr\{N(t+h) - N(t) \geq 2\} = o(h)$ for all $t \geq 0$ and $h > 0$.

In the above properties, the function $f(\cdot)$ is said to be $o(h)$ if $\lim_{h \rightarrow 0} \frac{f(h)}{h} = 0$. From these properties we observe that the rate or mean-value function of the NHPP $\{N(t) : t \geq 0\}$ completely characterizes the probabilistic behavior of the process. Thus the objective of modeling an NHPP is to define a rate function that closely represents the behavior

of the arrival process under study. In the next section we discuss nonparametric, parametric, and semiparametric methods for estimating an NHPP from observed arrival streams and for generating independent realizations of the fitted NHPP.

Nonparametric NHPP Methods

Leemis [9–11] develops a nonparametric method for estimating and simulating an NHPP. This method utilizes multiple observations of the arrival process over a given time interval $[0, S]$. The observed arrival times of these process realizations are superimposed, and the mean-value function over the observation interval is represented by a piecewise-linear estimator. The details of the method are as follows.

Given k independent realizations of the arrival process over the interval $[0, S]$. Let n_i be the number of arrivals observed on the i th realization for $i = 1, 2, \dots, k$. In addition, let $n = \sum_{i=1}^k n_i$ be the total number of arrivals accumulated over all realizations of the arrival process, and let $\{t_{(i)} : i = 1, \dots, n\}$ denote the overall set of arrival times for all arrivals expressed as an offset from the beginning of the observation interval $(0, S]$. Then sort the set of arrival times in increasing order represented by $t_{(0)} \equiv 0$ and $t_{(n+1)} \equiv S$ so that for $t_{(i)} < t \leq t_{(i+1)}$ and $i = 0, 1, \dots, n$. The resulting piecewise linear nonparametric estimator of $\mu(t)$ is

$$\hat{\mu}(t) = \frac{in}{(n+1)k} + \left\{ \frac{n[t - t_{(i)}]}{(n+1)k[t_{(i+1)} - t_{(i)}]} \right\}; \quad (1)$$

see Leemis [9]. Figure 1 depicts the structure of the estimator $\hat{\mu}(t)$.

Given the estimated mean-value function $\hat{\mu}(t)$ of the form (1), the inversion algorithm of Leemis [9] as displayed in Fig. 2 can be used to generate a stream of arrival times $\{A_i : i = 1, 2, \dots\}$ over the time interval $(0, S]$ with approximately the same general pattern of dependence on time as in Equation (1).

The main advantage of this approach to modeling and simulating NHPPs is that it does not require the assumption of any particular functional form for the way in which

the arrival rate $\lambda(t)$ depends on the time. Furthermore as the number of realizations k of the target arrival process becomes large, that is as $k \rightarrow \infty$, the estimated mean-value function $\hat{\mu}(t)$ of Equation (1) converges to the true mean-value function $\mu(t)$ for all $t \in (0, S]$ with probability 1. This means that the simulation algorithm given in Fig. 2 (which is based on inversion of $\hat{\mu}(t)$ so that $A_i = \hat{\mu}^{-1}(B_i)$ for $i = 1, \dots, N$) is also asymptotically valid as $k \rightarrow \infty$. For additional details on this approach to modeling and simulation of NHPPs, see Leemis [11].

Parametric NHPP Models

Parametric models for the rate function of an NHPP have been developed to represent arrival processes that exhibit systematic changes in the arrival rate over time such as long term trends or periodicities.

To represent arrival processes having a long term linear trend, Cox and Lewis [12] introduce an exponential linear rate function of the form

$$\lambda(t) = \exp\{\alpha_0 + \alpha_1 t\}. \quad (2)$$

This rate function has an exponential form to ensure that the arrival rate always remains positive. To represent more general long-term trends as well as cyclic behavior with a known frequency ω , Lewis [13] introduces a rate function of the form

$$\lambda(t) = \exp \left\{ \sum_{i=0}^2 \alpha_i t^i + \gamma \sin(\omega t + \phi) \right\}. \quad (3)$$

MacLean [14] proposes that any continuous rate function can be approximated arbitrarily closely using an exponential polynomial rate function of degree m

$$\lambda(t) = \exp \left\{ \sum_{i=0}^m \alpha_i t^i \right\}. \quad (4)$$

To model the occurrence of storms to an offshore drilling site, Lee *et al.* [2] use an NHPP with rate function of the form

$$\lambda(t) = \exp \left\{ \sum_{i=0}^m \alpha_i t^i + \gamma \sin(\omega t + \phi) \right\}. \quad (5)$$

Figure 1. Nonparametric estimator of mean-value function.

```

[1] Set  $i \leftarrow 1$  and  $N \leftarrow 0$ .
[2] Generate  $U_i \sim \text{Uniform}(0,1)$ .
[3] Set  $B_i \leftarrow -\ln(1 - U_i)$ .
[4] While  $B_i < n/k$  do
  Begin
    Set  $m \leftarrow \left\lfloor \frac{(n+1)kB_i}{n} \right\rfloor$ ;
    Set  $A_i \leftarrow t_{(m)} + \{t_{(m+1)} - t_{(m)}\} \left\{ \frac{(n+1)kB_i}{n} - m \right\}$ ;
    Set  $N \leftarrow N + 1$ ; Set  $i \leftarrow i + 1$ ;
    Generate  $U_i \sim \text{Uniform}(0,1)$ ;
    Set  $B_i \leftarrow B_{i-1} - \ln(1 - U_i)$ .
  End

```

Figure 2. Algorithmic statement of the NHPP simulation procedure of Leemis [9].

For efficient simulation of an NHPP with the rate function (5), the authors develop maxline, an algorithm to construct a piecewise linear majorizing rate function $\tilde{\lambda}(t)$ that closely approximates $\lambda(t)$ on $[0, S]$; that is, $\tilde{\lambda}(t) \geq \lambda(t)$ for all $t \in [0, S]$. The advantage of this approach is that the corresponding mean-value function $\tilde{\mu}(t) = \int_0^t \tilde{\lambda}(u) du$ is piecewise quadratic and thus, is easily inverted so that a sequence of arrivals can be easily generated by the method of inversion. Then applying the thinning scheme of Lewis and Shedler [15], the authors develop an algorithm to generate arrival epochs $\{A_\ell\}$ from an NHPP with rate function $\lambda(t)$ as follows: the epoch $\tilde{A}_n$ is independently accepted for inclusion in $\{A_\ell\}$ with probability $\lambda(\tilde{A}_n) / \tilde{\lambda}(\tilde{A}_n)$ for $n = 1, 2, \dots$.

Kuhl *et al.* [16] and Kuhl and Wilson [17] extended the work of Lee *et al.* [2] to handle arrival processes with a general trend

or multiple periodicities. The model for the arrival process is an NHPP with rate function of the form

$$\lambda(t) = \exp\{h(t; m, p, \Theta)\}, \quad t \in (0, S], \quad (6)$$

with

$$h(t; m, p, \Theta) = \sum_{i=0}^m \alpha_i t^i + \sum_{k=1}^p \gamma_k \sin(\omega_k t + \phi_k),$$

where $\Theta = [\alpha_0, \alpha_1, \dots, \alpha_m, \gamma_1, \dots, \gamma_p, \phi_1, \dots, \phi_p, \omega_1, \dots, \omega_p]$ is the vector of continuous parameters. Kuhl *et al.* [16] use a form of inversion for simulating NHPPs with a rate function of the form (6). Rate functions of this type were originally used in the UNOS Liver Allocation Model [3]; and although the resulting fits were remarkably accurate, the times to generate realizations of the fitted NHPPs were too large in practice.

An extension of the maxline procedure of Lee *et al.* [2] to yield a piecewise linear rate function that majorizes Equation (6) could facilitate rapid simulation of such NHPPs based on thinning, but substantial effort may be required to develop such a procedure.

Semiparametric NHPP Methods

Semiparametric methods for representing NHPPs have been developed in an attempt to combine the flexibility of nonparametric methods with the smooth, continuous representations of parametric models. Kuhl and Wilson [18] develop a nonparametric method for modeling and simulating arrival processes that may exhibit a long-term trend or nested periodic effects (such as daily and weekly cycles), where the periodic effects might not necessarily be symmetric. The method is referred to as a *multiresolution* procedure.

The multiresolution procedure of Kuhl *et al.* [19] involves the following steps at each resolution level corresponding to a basic cycle: (i) transforming the cumulative relative frequency of arrivals within the cycle to obtain a statistical model with approximately normal, constant-variance responses; (ii) fitting a specially formulated polynomial to the transformed responses; (iii) performing a likelihood ratio test to determine the degree of the fitted polynomial; and (iv) fitting to the original (untransformed) responses a polynomial of the same form as in (ii) with the degree determined in (iii). Given the fitted functions at each resolution, the multiresolution model is constructed for the mean-value function.

Extending the semiparametric method of Kuhl *et al.* [19] to model more general nonstationary behavior, Kuhl *et al.* [20] introduce an alternative method to model the mean-value function of the NHPP. The final estimate is obtained for the mean-value function of the following form:

$$\mu(t) = \mu(S)R(t) \quad \text{for } t \in [0, S], \quad (7)$$

where $R(t)$ is a monotone increasing degree- r polynomial of the form

$$R(t) = \begin{cases} t/S, & \text{if } r = 1, \\ \sum_{k=1}^{r-1} \beta_k (t/S)^k + \left(1 - \sum_{k=1}^{r-1} \beta_k\right) (t/S)^r, & \\ & \text{if } r > 1. \end{cases}$$

This methodology can be used to fit an NHPP to one or more realizations of data from the process under study. The primary advantage of this method is that it fits a smooth (differentiable) mean-value function over the interval $[0, S]$.

The fitting and simulation methods of Kuhl *et al.* [19,20] have been implemented in Web-based software, which is available on-line via <http://www.rit.edu/simulation>.

NONSTATIONARY NON-POISSON ARRIVAL PROCESSES

Although NHPPs are used to model a large class of nonstationary arrival processes, there are applications where NHPPs do not adequately represent the arrival process of interest. For an NHPP, the random variable $N(t)$ has the Poisson distribution with mean $\mu(t)$ for all $t > 0$, we also have $\text{Var}[N(t)] = \mu(t)$ for all $t > 0$; and thus, an NHPP has $\text{Var}[N(t)]/\text{E}[N(t)] = 1$ for all $t > 0$. In many studies of manufacturing systems, telecommunications networks, and consumers' purchasing behavior, the relevant point process exhibits a variance-to-mean ratio that is either substantially more or less than that of an NHPP.

Gerhardt and Nelson [5] propose methods for modeling and simulating a point process that allow the user to achieve desired values of both the mean-value function and the ratio $\text{Var}[N(t)]/\text{E}[N(t)]$ of the process. Starting from a stationary renewal process $\{N^\circ(t)\}$ with rate 1 and the desired ratio $\lim_{t \rightarrow \infty} \text{Var}[N^\circ(t)]/\text{E}[N^\circ(t)] = C$, a corresponding sequence of renewal epochs $\{A^\circ n : n = 1, 2, \dots\}$ for the process $\{N^\circ(t)\}$ is generated. Finally a point process $\{N(t)\}$ is obtained with the desired mean-value function $\mu(t)$ and the corresponding arrival epochs $\{A_n : n = 1, 2, \dots\}$ by inversion: $A_n = \mu^{-1}(A^\circ n)$ for $n = 1, 2, \dots$. The inversion

procedure yields $E[N(t)] = \mu(t)$ for all $t \geq 0$ and $\lim_{t \rightarrow \infty} \text{Var}[N(t)]/E[N(t)] = C$.

Gerhardt and Nelson [5] also propose a method for achieving a point process $\{N(t)\}$ with the desired mean-value function $\mu(t)$ based on thinning. If the corresponding rate function $\lambda(t) = \frac{d}{dt}\mu(t)$ has finite upper bound λ^* , then the authors start from a stationary renewal process $\{N^*(t)\}$ with rate λ^* , arrival epochs $\{A_n^* : n = 1, 2, \dots\}$, and the desired variance-to-mean ratio C ; and the corresponding sequence of arrival epochs $\{A_\ell : \ell = 1, 2, \dots\}$ from a point process with the desired mean-value function $\mu(t)$ is obtained as follows: the epoch A_n^* is independently accepted for inclusion in $\{A_\ell\}$ with probability $\lambda(A_n^*)/\lambda^*$ for $n = 1, 2, \dots$. The authors show that the resulting thinned point process $\{N(t) : t \geq 0\}$ has mean-value function $E[N(t)] = \mu(t)$ for all $t \geq 0$.

CONCLUSIONS

In this article we have surveyed nonparametric, parametric, and semiparametric methods for modeling and simulating NHPPs; and we have also reviewed similar procedures for handling nonstationary non-Poisson arrival processes. Although these methods can be used to model a large class of nonstationary point process, research into more flexible and more efficient methods for both modeling and simulating these stochastic processes is ongoing.

NURSE SCHEDULING MODELS

JONATHAN F. BARD
Graduate Program in Operations
Research and Industrial
Engineering, The University of
Texas, Austin, Texas

INTRODUCTION

Nurse scheduling has become the prototypical example of personnel scheduling in the service industry. Unlike manufacturing, where standard shifts and days off are the rule, service organizations often operate 24 h a day, 7 days a week, and face widely fluctuating demand. In hospitals and other health-care facilities, improperly balanced nursing teams are too often the explanation for excessive medical errors, substandard patient care, job dissatisfaction, and high turnover rates [1]. What sets the nurse scheduling problem apart from other staffing applications is the need to take into account an increasing variety of skill requirements, labor restrictions, union contracts, individual preferences, and uncertain demand, all of which conspire to frustrate quantitative approaches.

In the most general sense, personnel planning and scheduling problems can be viewed temporally and decomposed along the time axis. This suggests the following hierarchical breakdown:

- *Long-Term Planning* fix the size and composition of the permanent workforce.
- *Midterm Scheduling* determine days off, shift assignments, and optimal skill mixes.
- *Short-Term Scheduling* assign tasks to workforce, manage vacations and leave, plan for the use of overtime, casuals, and part-time labor.
- *Real-Time Control* adjust workforce to deal with emergencies, absenteeism, and other last-minute disruptions.

In the long run, the goal is to structure the permanent workforce. This may include different levels of full-timers, part-timers, casuals, and per diem nurses, each with different skill sets. The demand data used for the analysis are typically average values and hence do not directly take into account seasonal or weekly variations.

The output of the long-term analysis is the number of nurses (by type) that are required for each unit or ward, along with a set of shift profiles. Hospital units use this information as input to the midterm scheduling problem, the next level in the hierarchy. The primary goal at this level is to generate nurse rosters, that is, patterns of days on and days off over a 2- to 6-week planning horizon. In the more traditional case, fixed patterns of days on and days off are established and the staff is rotated continuously through them; for example, see Ref. 2. At this level, *rostering* and *scheduling* are used interchangeably.

Alternatively, many hospital units have turned to methods that give individuals more control over their assignments and management more flexibility in the face of shortages. *Self-scheduling*, for example, uses a sign-up procedure [3]. Nurses are asked to sign up for those shifts that they wish to work over the planning horizon. When conflicts occur, the nurse manager tries to resolve them through consensus, often a difficult process.

A second approach, *preference scheduling*, applies a common set of rules and a cost measure that together are designed to achieve a balance between staff satisfaction and the use of external resources. The rules (constraints) are hospital-dependent but generally may be categorized as either hard or soft. When the rosters are maintained from one planning period to the next, we have what is sometimes called *cyclic scheduling*. In today's environment, it is more common

for rosters to be rebuilt from scratch, starting from a template or sign-up schedule.

In the short run, schedule adjustments must be made on a weekly and daily basis to account for planned leave and expected departures from average demand. To accomplish this, critical resources must be tracked and evaluated. The goal is to provide updated schedules that balance overtime and the use of part-time labor so that all requirements are met at minimum cost and without too much disruption to the midterm rosters. This can be thought of as a replanning problem.

Given the current schedules, further adjustments and decisions need to be made on a shift-by-shift basis to accommodate changing circumstances. When supply exceeds demand in a unit, a nurse may be asked to float to another unit or may be sent home. When a unit is short of staff, the hospital has several options such as requesting overtime, calling in casuals, asking a nurse to work on his or her day off, or requesting outside resources. The outside resources include a float pool and agency nurses. Each option has different cost consequences.

At the bottom level of the hierarchy, a real-time scheduling problem that falls under the heading of *control or disruption management* must be solved. The goal is to get back on track as soon as possible, at minimum cost and with minimum deviation from the original schedule.

The idea of decomposing planning problems along the time axis is an effective way of dealing with uncertainty. At each level, solutions are obtained using the best estimates of the uncertain parameters. As the time horizon shrinks and the uncertainty unfolds, adjustments are made; however, all higher level decisions remain in effect and become inputs at subsequent levels. An alternative to the hierarchical approach might be an integrated approach that accounts for the stochastic nature of demand in a single model. Although the field of stochastic optimization is growing, there have been few, if any, attempts to formulate and solve stochastic versions of the nurse scheduling problem due to its size and complexity [for a stochastic model developed for assigning nurses to patients, see Ref. 4].

Whether specialized to nurses or to other service sector workers, personnel scheduling problems are generally NP-hard in the strong sense [5]. In this article, we focus mainly on the midterm problem, which has received the lion's share of attention, but also mention some recent advances related to short-term adjustments. The long-term and real-time problems are not as well studied with respect to nurse staffing, so there is little to say [see Ref. 6 for one approach to estimating long-term nurse staffing needs, and Ref. 7 for a different application]. In the next section, the basic elements of the staffing problem are introduced, followed by an overview of models for midterm and short-term scheduling. The relevant literature is summarized in the section titled "Past and Current Research." We close with an assessment of current capabilities and suggest several topics for future research.

MODELING ISSUES

Hospitals in the United States typically employ full-time nurses to work either 8- or 12-h shifts, giving rise to five standard shift types: three 8-hour shifts called *Day* (7 a.m.–3 p.m.), *Evening* (3 p.m.–11 p.m.), *Night* (11:00 p.m.–7 a.m.) and two 12-hour shifts called *AM* (7 a.m.–7 p.m.) and *PM* (7 p.m.–7 a.m.). An AM shift starts at the same time as a Day shift and ends midway into the Evening shift. A similar interpretation exists for a PM shift. Part-time nurses may work a full shift or a fraction thereof. European hospitals have a parallel structure but may use up to 10 standard shift types.

Staffing requirements for a unit depend on the census (typically taken at midnight), the acuity or level of infirmity of the patients, and the time of day. Nurse rosters are usually generated 2 weeks prior to the start of the upcoming planning period which may extend anywhere from 2 to 6 weeks. Adjustments are made weekly and daily to account for call outs and other disruptions.

For modeling efficiency, it is convenient to divide the day into a set of contiguous (hourly) periods of uneven length such that each shift consists of one or more periods.

Figure 1. Shift types and demand periods.

By doing so, we can express the demand in terms of periods rather than shifts and hence reduce the size (number of rows) of the model. Figure 1 depicts the relationship between shifts and periods for our problem. As can be seen, only four periods are needed to cover 24 h. The first demand period coincides with the Day shift, the second period covers the first half of the Evening shift, the third covers the second half of the Evening shift, and the last coincides with the Night shift.

In developing a model, coverage constraints are needed to account for demand by skill category for each period, regardless of timescale. The nursing staff at most US hospitals includes registered nurses (RNs), licensed practical nurses (LPNs), technicians (TECHs), and nurse aides (AIDEs). Each category may be further divided by specialty and experience, the latter being a chief determinant of quality of care. RNs are the most versatile and are generally preferred because they can provide the widest range of care. LPNs are less flexible, while AIDEs have only limited training and skills. TECHs are commonly called upon to operate certain medical instruments specific to a unit, such as cardiology. For purposes of matching skills with requirements, some percentage of the average daily demand is assigned to each nurse category. The specification of this percentage is a management decision that represents a tradeoff between cost, availability, and quality of service. European health-care systems follow similar procedures and likewise group nurses by skill, but use more grades within each category.

MIDTERM SCHEDULING

When constructing midterm rosters, the process can be confined to a single nursing unit at

a time since there are few interdependencies among them. In addition, each skill category can generally be scheduled separately. When higher skilled personnel are permitted to fill in for lower skilled personnel, the process is called *downgrading* and leads to a more efficient use of the workforce. Bard and Purnomo [8] provide a series of algorithms for the corresponding problem.

An important component of nurse scheduling is the perception of fairness. When preferences are included in the process, soft constraints are used to embody the scheduling rules [9–12]. Some examples are given below:

- Number of one day-off or one day-on patterns occurring in a schedule. The higher the number, the worse the schedule. Such patterns are commonly referred to as on-off-on and off-on-off patterns, and written 1-0-1 and 0-1-0, respectively.
- Number of shift changes on consecutive days. Five-day schedules that have many shift changes, such as Day-Evening-Day-Evening-Day, are undesirable.
- Working three or more shifts in two consecutive weekends.
- No AM or Day shift after a requested day off or holiday. No PM or Night shift before a requested day off or holiday.

The most prevalent hard constraints are as follows:

- Nurses must be assigned to work as many hours as their contract specifies. Overtime is possible but it is generally considered in the daily adjustment stage.
- A nurse can work at most 12 h in 24 h. This means that at most one shift type can be assigned in a day. Also, consecutive shifts must be separated by at least 8 h.
- Rotational nurses must be assigned a minimum proportion (typically 40%) of each of the two shift types specified in their individual contracts. Nonrotational nurses can only be assigned to

work the shift type specified in their contracts.

- The number of consecutive working days (i.e., *workstretch*) should not exceed a specified number of days.
- Every nurse must work two weekend shifts every 2 weeks.

Two versions of the midterm scheduling problem are highlighted below and have their foundations in the pioneering work of [13,14]. Because of the possibility of staffing shortages, uncovered demand is identified as gaps in the schedule to be filled in on the actual day.

Preference Scheduling

In the development of the midterm scheduling model, we make use of the following notation.

Indices and Sets

- i index for nurses; $i \in N$
- j index for schedules; $j \in S_i$ nurse i
- p scheduling period (portion of a day); $p \in P$
- d day of the week; $d \in D$
- N set of nurses to be scheduled
- S_i set of schedules considered for nurse i
- P set of periods in a day
- D set of days in the planning horizon

Parameters and Data

- c_{ij} penalty “cost” of assigning schedule j to nurse i (this value is a function of the number and severity of preference and request violations in the schedule)
- a_{ijdp} 1 if schedule j for nurse i contains period p on day d , 0 otherwise
- LD_{dp} lower bound on demand for nurses on day d in period p
- UD_{dp} upper bound on demand for nurses on day d in period p
- M_p large number representing the cost of an outside nurse or under coverage in period p

Decision Variables

- x_{ij} (binary) 1 if nurse i is assigned to schedule j , 0 otherwise
- y_{dp} number of outside nurses used on day d in period p
- s_{dp} slack variable for the “left” constraint on day d in period p

A basic optimization model designed to minimize the cost of meeting the demand for a particular nurse category in each of the $m \equiv |P| \times |D|$ periods over the planning horizon, is given below in column-oriented format.

Minimize

$$\sum_{i \in N} \sum_{j \in S_i} c_{ij} x_{ij} + \sum_{d \in D} \sum_{p \in P} M_p y_{dp} \quad (1a)$$

subject to

$$-s_{dp} + \sum_{i \in N} \sum_{j \in S_i} a_{ijdp} x_{ij} + y_{dp} = LD_{dp},$$

$$\forall d \in D, p \in P \quad (1b)$$

$$\sum_{j \in S_i} x_{ij} = 1, \quad \forall i \in N \quad (1c)$$

$$x_{ij} = 0 \text{ or } 1, \quad \forall i \in N, j \in S_i \quad (1d)$$

$$0 \leq s_{dp} \leq UD_{dp} - LD_{dp}, y_{dp} \geq 0, \quad \forall d \in D, p \in P. \quad (1e)$$

The objective (1a) is to minimize the weighted sum of the costs associated with the schedules assigned to the regular nurses and the cost of using outside nurses to cover gaps. The choice of the parameter M_p implicitly defines the tradeoff between satisfying the collective preferences of the nursing staff and incurring additional costs by calling on outside nurses to meet unfilled demand. In general, we want $M_p \gg \max\{c_{ij} : i \in N, j \in S_i\}$ to ensure that costs are minimized before preferences, although other options are possible.

The first constraints (1b) ensure that the number of nurses scheduled in each period falls between some minimum and maximum value, and can be written as two separate constraints. In many situations, it might only be necessary to include the lower bound

component. Constraints (1c) along with (1d) guarantee that each nurse in the unit is assigned one and only one schedule. Note that for the sake of compactness, it is possible to combine d and p into a single index that references the time period over the planning horizon. Finally, observe that as long as LD_{dp} and UD_{dp} are integral, an optimal solution will always exist with s_{dp} and y_{dp} integral so it is not necessary to declare them as such.

Both exact and heuristic methods have been developed to find solutions to model Equations (1a–1e) and its variants. Column generation was used successfully by Bard and Purnomo [10] and Jaumard *et al.* [15] while Aickelin and White [9] implemented a tabu search approach. Further discussion of solution methodologies is given in the section titled “Past and Current Research.”

Cyclic Scheduling

In a cyclic scheduling environment, a portion of the staff has rotational shift profiles [16]. A profile specifies the shift types and the number of hours that a nurse is to be assigned over the planning horizon. Problem inputs include the number of nurses for every shift profile, demand per shift, and scheduling rules. When 8- and 12-h shift combinations are permitted, there are many possible shift profiles; that is, Day–Evening, Day–Night, Day–PM, Evening–Night, AM–Evening, AM–Night, and Day–PM.

The second input, demand, may be stated as a range in terms of the number of nurses needed for every shift. Specific values are easily converted to demand per period. The rules typically used in cyclic scheduling are associated with the days-on and days-off patterns listed above as soft constraints.

In preference scheduling, a column-oriented model is best because of the ease with which rule violations can be incorporated. Such models, however, become increasingly difficult to solve as the number of nurses in a unit grows. Because cyclic scheduling considers far fewer rules, a constraint-oriented formulation would seem to be a better choice [14,17]. The main

change with respect to the model expressed in Equations (1a–1e) involves the definition of the decision variables. For cyclic scheduling, the primary decision variables, denoted by x_{idt} , take on the value of 1 or 0 depending on whether or not nurse i is assigned to work on day d and shift t . As a result, the rules that determine the legality of a schedule (hard constraints) or measure preference violation (soft constraints) are required to be modeled explicitly as constraints. For days-on and days-off pattern violations, we have the following:

$$\begin{aligned} \sum_{t \in T_i} x_{idt} + \left(1 - \sum_{t \in T_i} x_{i,d+1,t}\right) \\ + \sum_{t \in T_i} x_{i,d+2,t} + p_{id} \geq 1, i \in N, \\ d = 1, \dots, |D| - 2 \end{aligned} \quad (2a)$$

$$\begin{aligned} \left(1 - \sum_{t \in T_i} x_{idt}\right) + \sum_{t \in T_i} x_{i,d+1,t} \\ + \left(1 - \sum_{t \in T_i} x_{i,d+2,t}\right) + q_{id} \geq 1, \\ i \in N, d = 1, \dots, |D| - 2. \end{aligned} \quad (2b)$$

where p_{id} is a binary variable equal to 1 when nurse i has off–on–off pattern that starts on day d and 0 otherwise, and q_{id} is a binary variable equal to 1 when nurse i has on–off–on pattern that starts on day d and 0 otherwise, and T_i is the set of shifts for which nurse i is hired to work. A complete model can be found in Ref. 17.

SHORT-TERM SCHEDULING

There are several levels of authority and responsibility within a hospital with respect to staff scheduling. At the unit level, the nurse manager, clinical manager, or charge nurse keeps track of the current situation and assesses whether the level of coverage is too low, appropriate, or too high for the number of patients and their acuties. When more nursing resources are available in a unit than are needed for a particular shift, the nurse

manager has several options. Beginning with the least senior staff member, the first is to request a reassignment to another unit. If the nurse in question is not willing to float and is not contractually obligated to do so, her shift is cancelled and her supervisor notified. Generally speaking, nurses would rather be cancelled than floated, although individual preferences may be overridden when the need is critical. If a nurse is cancelled, then one of the following designations is used for the time off: vacation, personal day, holiday, or unpaid leave. This information is reported to the nursing resources director.

Daily Adjustments

When a unit is short of staff, a number of corrective steps can be taken. Each has different cost consequences, although in most hospitals cost is not foremost on the minds of those directly responsible for a unit. Their primary concern is meeting demand, especially in critical situations. With this in mind, the order of action is typically as follows:

1. look for volunteers in the unit to work the next shift (or fraction thereof) as overtime;
2. call casuals and per diem nurses;
3. find floaters from other units that might be overstaffed or draw on the float pool;
4. cycle through the on-call list (used mostly in emergencies);
5. have the nursing resources director call in agency nurses;
6. try to reach unit staff who are not scheduled to work during the next 24 h;
7. invoke mandatory overtime by requesting that a nurse on the current shift stay for the next shift. This is done in reverse order of seniority on a rotating basis so the most junior nurse is not necessary singled out.

Several caveats and qualifications exist for each of these options. For example, when assigning either voluntary or mandatory overtime, there is a distinct possibility that the nurse will call in sick another day during

the pay period. Although he or she will not be paid overtime if his or her total hours do not exceed 80 in the 14-day period, there are no negative consequences. In effect, he or she works overtime in exchange for a day off. A similar situation arises in practice when a nurse is called in on the day off, to work a shift that is separated from the upcoming shift by only 8 h (e.g., Evening $\rightarrow$ Day). In this case, he or she is likely to call in sick for the day shift so little has been gained. This is called a *double back* and should be avoided.

The first two options fall within the purview of the unit manager and are not necessary to model. If contributions are to be made at this level, it is best to focus on the hospital-wide problem of optimally allocating floaters, on-call nurses, and agency nurses. This problem must be solved at least three times a day, and falls within the purview of the nursing resources director.

Modeling Approach

The majority of rules and constraints that govern the daily short-term scheduling problem are outlined above. The complete set may vary among hospitals but generally reflects institutional policies, union agreements, state or federal statutes, and financial considerations. The overall goal is to satisfy coverage requirements at minimum cost while taking into account nurse preferences, morale, the need for the perception of fairness, and the expected response of staff members whose work patterns are affected.

Bard and Purnomo [18] were the first to address this problem analytically by developing an integer linear program for a 24-h planning horizon of three shifts. They proposed that the solutions be implemented within a rolling horizon framework since staffing requirements change unpredictably over the day.

In formulating the model, it was assumed that all cancellation and overtime costs were known, that demand was given or could be estimated accurately for each of the three shifts in the planning horizon, and that the status of all unit nurses, pool nurses, casuals, and agency nurses was available. This is equivalent to saying that the nurse managers, supervisors, and nursing resources

director all have up-to-date information on call outs, shortages, surpluses, floaters, and pool nurses. Using a branch-and-price algorithm, the authors were able to find optimal solutions to instances with up to 200 nurses within a few minutes.

PAST AND CURRENT RESEARCH

The overwhelming majority of research on nurse scheduling has centered on the midterm problem [19,20], which, as mentioned, has been viewed at least three different ways. When rotational or cyclic scheduling is used, several sets of rosters are generated that collectively satisfy the demand requirements. Nurses are then rotated from one set to another in consecutive planning periods. In the simplest case, an exact solution can be found by using a pure set covering model in which cyclic work patterns are generated to minimize the size of the nursing staff needed to cover the demand. Burns [21] studied the case of 10 days on for a 14-day planning horizon with every second weekend off and workstretches limited to six consecutive days. Although easy to implement, cyclic schedules impose a rigidity that many nurses find objectionable.

In contrast, self-scheduling attempts to solve the problem in a more flexible way. Having determined the staffing demand for each period, nurses are asked to sign up for any shifts that they want to work during the planning horizon as long as they remain within their contractual bounds. To avoid an oversupply in any given period, an upper limit is placed on the number permitted to sign up in each block of time. When conflicts occur, further adjustments are made through consensus. Griesmer [3] reported a successful application involving 32 nurses. Although the approach is appealing, it is quite difficult to implement because of the impracticality of holding meetings to resolve conflicts, especially for large units. Moreover, the results may not necessarily be perceived as fair. Those who are savvy enough to game the system will always have an advantage over the procrastinators. Controlling the sign-up order and rotating it over the year is the common way of dealing with this concern.

The third approach—preference scheduling—is actually a combination of the first two. Preferences can be measured in terms of requests to work specific shifts or to be given specific days off, and by other rules such as the number of working hours, shift sequence patterns or even nurse-to-patient ratios. Like self-scheduling, nurses are asked to sign up for shifts prior to the beginning of the planning horizon. At that time, they usually submit a list of requests to the nurse manager who compiles them and decides which to approve immediately in light of the coverage requirements for the upcoming planning horizon. When generating the final rosters, he or she tries to satisfy as many preferences and pending requests as possible.

Exact methods, heuristics, and constraint satisfaction have all been applied to the preference scheduling problem over the last 25 years. Exact methods primarily involve the use of set covering-type models like Equations (1a–1e). In this approach, alternative rosters are generated by any number of methods and one is selected for each nurse. The typical objective is to minimize a weighted combination of costs and preference penalties. What has limited the usefulness of this approach is the size of the integer programs (IPs) that must be solved, and the determination of the penalty coefficients. The longer the planning horizon, the more alternatives that can be generated, and as a result, the harder the IP is to solve.

Warner [22] was the first to develop a methodology for solving the set covering model for the case in which all nurses work 8-h shifts. Jaumard *et al.* [15] extended his model to include both 8- and 12-h shifts, and different skill levels. This extension adopted the concept of periods rather than shifts as the basic time unit. The modified problem was then solved using Dantzig–Wolfe decomposition with the necessary adjustments for integrality restrictions. Columns were generated at each iteration by solving a resource-constrained shortest path subproblem, one for each nurse.

While the set covering methodology focuses on strategies for generating candidate rosters in the form of columns,

heuristics are designed to first obtain an initial solution and then improve upon it with neighborhood search. Miller *et al.* [13] used a simplified version of a rotation heuristic for a 4-week problem. The objective function was a weighted combination of personnel costs and preference penalties. A greedy heuristic with feasible neighborhood swaps was adopted to solve a real instance with up to 12 nurses, a difficult problem at the time.

Metaheuristics have also been used for preference scheduling. Dowsland [23] developed a tabu search approach with strategic oscillation. The algorithm starts with an initial roster obtained with a greedy heuristic that ignores the minimum coverage requirement and treats each nurse separately. In the next phase, three swap moves are used to try to satisfy the coverage constraints: shift swaps for a single nurse, two-nurse chain swaps, and rotation swaps. The quality of each schedule produced by the algorithm is measured by a weighted sum of the penalty coefficients associated with the preference violations.

Valoux and Houxos [14] used a combination of integer programming and heuristics to find solutions to a limited version of the preference scheduling problem. Instead of solving the classic set covering model, they solved a relaxation that minimized the total number of shifts needed to satisfy demand subject to several preference constraints. Arthur and Ravindran [24] were the first to apply goal programming to the preference scheduling problem. They considered the following four goals: contractual requirements, preferences, requests, and staffing requirements. In the first phase of their two-phase approach, a small IP is solved to decide the days on which each nurse is to work. Shift assignments are made in the second phase. In a similar vein, Berrada *et al.* [11] proposed a constraint satisfaction model that viewed demand coverage and the number of working days as the hard constraints and compliance to shift patterns, daily requirements for supervisory personnel, and the grouping of days off and weekends off as the soft constraints. Several solution approaches were discussed

including sequential optimization and tabu search.

For the same problem, Ferland *et al.* [12] developed a tabu search algorithm that included a diversification strategy and an adaptive memory structure. Similarly, Burke *et al.* [25] used tabu search to schedule nurses at several Belgium hospitals using a code implemented in the Plane software system. Subsequent refinements allowed for multiple objectives and more equitable weekend assignments.

Working independently, Cheng *et al.* [26] proposed about 20 heuristic rules to build rosters and recursively fill in the uncovered shifts. Following a different course, Kawanaka *et al.* [27] used a genetic algorithm to find solutions. Their method was a bit restrictive, though, because it was designed around six hard constraints specific to the hospital environment in which they were working. Other heuristics include the use of language theory, artificial intelligent techniques, and expert systems. The general idea is to represent problem constraints as clauses or strings that can be combined to form feasible schedules with the help of an inference engine like Prolog; for example, see Ref. 28.

Table 1 summarizes the work on exact and heuristic methods for midterm preference scheduling. The first column lists the researchers, the second column identifies the type of model used, and the last column highlights the solution methodology.

Somewhat surprisingly, only a handful of the approaches discussed in this section have found their way into commercial systems. The first was the work of Warner [22] who developed ANSOS in the late 1970s and who went on to develop ClairVia in the 1990s. More recently, the column generation approach of Bard and Purnomo [10] was realized in a system called *CareWare*. Over the years, many products have appeared, but few have taken advantage of the sophisticated techniques that have emerged from academic research, preferring instead to rely on simple rules and heuristics. This issue is further discussed by Kellogg and Walczak [29] who trace the transfer of nurse scheduling technology from academia to the marketplace.

Table 1. Summary of Midterm Scheduling Research

Researchers	Model Type	Solution Methodology
Aickelin and White [9]	Set covering	Genetic algorithm
Arthur and Ravindran [1]	Constraint-based	Goal programming
Bard and Purnomo [18]	Set covering	Column generation
Berrada <i>et al.</i> [11]	Constraint-based	Sequential optimization, tabu search
Cheng <i>et al.</i> [26]	Rule-based	Constraint programming
Dowland [23]	Set covering	Tabu search
Ferland <i>et al.</i> [16]	Constraint-based	Goal programming
Griesmer [3]	Implicit	Self-scheduling (sign-up)
Jaumard <i>et al.</i> [15]	Constraint-based	Dantzig–Wolfe decomposition
Kawanaka <i>et al.</i> [27]	Constraint-based	Genetic algorithm
Millar and Kiragu [2]	Constraint-based, network	Integer programming
Miller <i>et al.</i> [13]	Constraint-based	Greedy heuristic
Okada [28]	Logical clauses	Inference engine
Purnomo and Bard [17]	Constraint-based	Dantzig–Wolfe decomposition
Valouxis and Housos [14]	Constraint-based	Integer programming, heuristics
Warner [22]	Constraint-based	Integer programming

CONCLUSIONS

The continuing interest in nurse scheduling is driven by a combination of (i) the economic importance of the application, (ii) the enticing duality between the conciseness of the problem statement and the difficulty in deriving high quality solutions, (iii) the opportunity to advance the use of quantitative methods, and (iv) the rewards that come from industrial–academic collaboration. Although variations of the problem have been studied exhaustively for many years, a broad survey of the field suggests that many opportunities still exist for improving both, the prevailing models and our algorithmic capabilities, especially when it comes to incorporating uncertainty in the analysis. A more robust treatment of demand at all four planning levels and a better understanding of long-term staffing requirements, are two areas where good research is needed.

To narrow uncertainty, it will be necessary to develop better forecasting systems and better patient tracking methods. Each of these functions requires the collection and analysis of massive amounts of data drawn from the various and often incompatible databases that have come to characterize the state of information technology at most health-care facilities. To overcome this hurdle, an important step will be the establishment of

standard patient records and uniform interface protocols.

DISTINCTIVE FEATURES IN OLYMPIC GAMES

Applications of operations research (OR) and management science (MS) in sports comprise quantitative support tools for measuring and improving players' and teams' performances, analyzing league strategy, and assessing social and economic values of professional sports. One typical application is to help the sports teams to choose their best available players in a sports league [1]. A collection of articles that best represents the sports research using Statistics and Operational Research can be found in Refs 2 and 3, respectively. What distinguishes Olympic Games and characterizes OR/MS specific applicable techniques is to be seen in the following text.

The Olympic Games were named after the place where they were held, in a sanctuary site for the Greek deities in Olympia near the towns of Elis and Pisa, in Southern Greece. Since ancient Greece, though designed for individual contests the cities from where the winners originated would grant them numerous prerogatives, showing that the city felt that it had won as well. The modern Games, initiated in 1896 by Baron Coubertin, intended to preserve the initial spirit of individual competitions. Until 1908, athletes entered as individuals rather than as members of a national team. However, the scenario preceding Second World War contributed to reverse this view, when the Third Reich had tried to show the supremacy of the Arian race in the Games of 1936, although the results were quite different from those what Hitler had expected.

During the Cold War, the national character of the contest became even more noticeable and developed into a true battle between East and West. Not the individual performances but the national performances were in the focal point of attention.

Nowadays, the results at country levels are disclosed through the Organizing Committee of the Olympic Games (OCOG) reports and in the popular media, playing an important role on the self esteem of an entire nation as a symbolism for achievement.

Therefore, the first distinguishing requirement of applied quantitative methods in Olympic Games is to help in explaining the results and setting targets for contestant countries consistent with available resources.

The second important issue brought about by Olympic Games concerns the capacity of shaping and projecting images of the host country, both domestically and globally. The event fosters an enhanced sense of national pride and makes the venue and the host country highly attractive for political and economic elites [4]. OR applications also aim to help the host country providing successful integrated planning and execution of activities. This is in consonance with the broader perspective of OR formulated by Ackoff [5] and Rosenhead [6], among others, encompassing both structuring and solution of real-world problems. The schema in Fig. 1 is a tool borrowed from problem structuring methods [7] for representing elicited knowledge and synthesizes the rationale behind this twofold competitive-integrative approach to Olympic issues.

UNDERSTANDING OLYMPIC PERFORMANCE

Explaining and understanding awarding Olympic medals as a function of country resources is the formal counterpart for the country competition, which is an Olympic driving force. So this will be the initiation for applications of quantitative methods to Olympics.

Figure 1. Rationale behind OR/MS applied to Olympics.

For the sake of motivating the theme, see in Ref. 8 the interesting debate about which explanatory variables play a causative role in awarding medals, illustrated by the proposal of dividing the total number of medals by the population of each country. It was first suggested in the “Globe and Mail,” analyzing the Atlanta games of 1996 and later in the “Los Angeles Times,” regarding the Beijing games of 2008. In the latter, the authors claimed to reflect real national accomplishment, since countries present huge differences in population scale. A forceful discussion follows, where opponents suggest several other relevant explaining variables, such as GDP funding (private or public) and delegation size. A large population offers a larger pool of potential athletes from which to withdraw successful contenders. High GDP allows to support higher fixed costs of infrastructure

and facilities for training and still to face the costs necessary to send athletes to the Games. Actually, understanding Olympic success requires additional explanatory variables, as demonstrated by the 1996 Olympic results, where Cuba won 25 medals, while India won 1 medal.

The second issue in Olympic performance regards the medals ranking, since results are traditionally published as a table in which countries are ranked in accordance with the number of gold medals their athletes have won. Silver medals are counted to break a tie and so are bronze medals in the sequence. This type of ranking is characterized as the lexicographic multicriteria method, where each criterion enjoys the exclusivity privilege by its turn. In this particular case, it implies a disadvantage to overvalue the gold medal, since countries that win the highest number

of silver and bronze medals but none of gold are ranked below countries that win a single gold medal.

Condon *et al.* [9] computed total scores (defined by the weighted sum of the top eight places in each event) for 195 countries that were represented at the 1996 Summer Games and gathered information on 17 independent variables. Acknowledging that usual explanatory variables would be connected to population density, economic system, and geographic distance, they included transportation indices in neural network and regression models, finding that “total length of railroad track” and “number of airports with usable runways” contributed to the explanation of variance in the Olympic scores. However, they conclude that “Although a country could use our models and new data to predict its total score in an upcoming Olympics, there is probably not much a country can do (in the short term) to make significant changes in the hope of increasing its total score.” In fact this applies to the left side of Fig. 2 where we display causal variables at the country level, but not to the right side, where we show the personal level explanatory variables.

Morton [10] performed statistical analysis for allometric approaches to medal scores, which included medals per capita, medals by GDP, and medals adjusted by several adjustment measures.

Hoffmann *et al.* [11] reported the results of regressions, testing hypotheses concerning the medal winning success of Olympic teams. They find that, while traditional economic and political factors are important, many inherent national characteristics such as geographical, demographic, and cultural factors have a significant and pronounced impact. The authors conclude that scope for public sports policy exists and discusses the degree to which the inherent characteristics limit it.

Bernard and Busse [12] examined the determinants of Olympic success at the country level and referred to fairness in achievements as a relevant issue. They asked, “Does the United States win its fair share of Olympic medals? Why does China win only 6% of the medals even though

it has one-fifth of the world’s population?” They considered the role of population and economic resources in determining medal totals from 1960 to 1996, suggesting that both a large population and a high per capita GDP are needed to generate high medal totals. They also provided out-of-sample predictions for the 2000 Olympics in Sydney.

According to Hawksworth [13], Head of Macroeconomics PricewaterhouseCoopers, “the number of medals won increases with the population and economic wealth of the country, but less than proportionately: David can sometimes beat Goliath in the Olympic arena, although superpowers such as the United States, China, and Russia continue to dominate at the top of the medal table.” This model includes data on medal performance from the Olympic Games since 1988, for the following statistically significant factors: population, average income levels, whether the country was previously a part of the former Soviet bloc (including Cuba in this case), whether the country is the host nation, and its medal share in the previous Olympic Games.

Courneya and Carron [14] identified three factors that can account for home advantage of the host nation, namely, crowd, learning, or familiarity and travel.

- Crowd may either influence players to play more recklessly or affect the match officials’ decisions to favor the home side. Crowd noise would appear to influence the observers to favor the home side and penalize the opponent side. In gymnastics, Ansorge and Scheer [15] found that judges at the 1984 Olympics not only scored their own gymnasts higher, but also that they scored immediate competitors lower. Balmer *et al.* [16] used simple statistical sign tests to identify bias demonstrating a clear observed imbalance. Corrective methods have been adopted to reduce nationalistic bias.
- Familiarity comprises the competition site and the cultural/environmental adaptation. Home advantage results relevant for events where there is wide variation in conditions (e.g., alpine

Figure 2. Explanatory variables for Olympic results at country and personal levels.

skiing, luge, and bobsled or where grass is used instead of artificial surfaces) as opposed to the far less variable rink size or stadia. Local athletes are more accustomed to facilities and they may be able to arrange more convenient locations and training schedules.

- Pace and Carron [17] proposed that “only a small portion of the variance in the home advantage/visitor disadvantage can be explained by travel related factors.” Jehue *et al.* [18] found direction of travel and time of day to be important, and suggested a possible “jet-lag” effect.

Balmer *et al.* [16] test for the prevalence of subjective officiating, distance traveled, and familiarity with local conditions, using linear, quadratic, and exponential terms in regression analysis. They conclude that subjective assessment by officials can explain a large proportion of the variation in observed home

advantage in Winter Olympic events. Familiarity with local conditions was shown to have an intermediate influence and no appreciable trends were noted for the travel factor, given that time would be available to overcome the latter adverse effects.

Kuper and Sterken [19] analyze Olympic participation and success in all the modern editions of the Summer Games, using a large data set including Olympic statistics, per capita income, and demographic information. They explain participation shares and medal success at the country level and show that, conditional on participation, it is possible to model success in the medal standings. They achieve the following conclusion:

- First, the economic condition of a country is still important for both participation and, to a lesser extent, for success. The impact of per capita income has diminished though. The same holds for

the impact of population size and distance to the Games.

- Second, the home effect is important, especially for participation. Here we have a regulated effect; the home team is allowed to send more athletes. This effect is still strong, but used to be more important at the older editions of the games. Probably, transport costs caused a bias to home representation. The home advantage in success is less clear. Before World War II the home advantage was strong via participation and success. At the recent games, the home advantage shifted from gold to bronze.
- Third, the legal tradition of a country, as a proxy of the sports culture is relevant for modeling participation and success. Especially, socialist countries send more athletes and earn more medals. French legal system countries are less impressive in their performance. Emancipation is found to be important. Media attention is also important in explaining participation. Finally, there seems to be an untested auto-regressive factor, since winning gold medals has important consequences for future success in the Olympics.

This is indeed, a fundamental task for quantitative models applied to Olympics: explaining success and failure in Olympic Games.

Lozano *et al.* [20] apply data envelopment analysis (DEA) to measure the performance of the nations participating in the last five Summer Olympic Games. The proposed approach considers two inputs (GNP and population) and three outputs (number of gold, silver, and bronze medals won). To increase the consistency of the results, weight restrictions are included, guaranteeing a higher valuation for gold medals than for silver medals and higher for the latter than for bronze medals. Variable returns to scale are assumed. In addition, plotting the performance of a specific country for the different games can help identify trends as well as objective successes and disappointments.

Lins *et al.* [21] proposed a zero sum gains data envelopment analysis (ZSG-DEA) model to assess Olympic performance of countries constrained to a bounded amount of medals. The weights assigned to each medal— w_G (gold), w_S (silver), and w_B (bronze)—can vary, allowing for different country preferences, though restricted by $w_G > w_S > w_B$. The ZSG-DEA assumes that the sum of outputs is constant. This is similar to a zero sum game in which whatever is won by a player is lost by one or more of the others. The overall changes are taken into account when measuring the efficiency of a given country.

Churilov and Flitman [22] focused on the issue of whether it is possible to design an objective impartial system of analysis of the Olympic results. The authors' approach aims at accounting for the multiple criteria and multiple attribute nature of the situation under consideration. Differentiation between results and performance reflects the concept of fairness, as a concern with "significant bias towards countries with large population, or rich countries—those whose GDPs are significantly higher than the average." The authors are quite persuasive putting their argument straightforwardly: "in order to financially afford getting 10 gold medals at Sydney Olympics, the United States of America would have had to spend 0.04% of its annual health budget, or 0.09% of its annual education budget, or 0.15% of its annual defense budget. For Australia, these numbers are 1.2%, 1.9%, and 4.9%, respectively, while for Laos they are 570%, 237%, and 146%, respectively (expressed in terms of 1998 USD)." The unsupervised data mining technique of self-organizing maps is used to group the participating countries into homogenous clusters. A DEA-based model is then used for producing a new ranking of participating teams that could be acceptable as "fair" by the majority of participants. An important innovation was the inclusion of disability adjusted life expectancy (DALE) index and index of equality of child survival (IECS).

Li *et al.* [23] formulate a context-dependent DEA model using different weight restrictions to analyze the achievements of nations during six Summer Olympic Games.

They report the efficiency scores showing that Australia, Norway, North Korea, and Azerbaijan, present very positive trends in terms of performance improvement.

Wu *et al.* [24] applied DEA to the last six Summer Olympic Games and obtained a unique ordering of the participant countries based on the average cross efficiency, also cluster analysis technique was used to select the more appropriate targets for poorly performing countries to use as benchmarks.

Wu *et al.* [25] proposed to apply a DEA game cross-efficiency model where each DMU is viewed as a competitor under a noncooperative game approach. The method is applied to the last six Summer Olympic Games.

The explanatory approach to Olympic results could be further extended to help guiding country strategies, when individual strategic features are included in assessment. Recent practices of the National Olympic Committees have moved away from funding mass participation and toward rewarding medal production [26]. Russia and China have long been funneling money to sports that offer multiple medal opportunities, such as diving, gymnastics, track and field, and swimming [27]. Until 2000, in the United States, the USOC was still dividing

up its funds equally among 45 different sports federations for use as they saw fit. In 2004, the USOC shifted to what it called a *venture capital* model requiring member National Governing Bodies (NGBs) to present specific plans detailing how they intend to use financial resources from the USOC to increase their chances of winning Olympic medals. Just as business executives, Olympic coaches in the United States now must present specific plans detailing how they intend to use the money to increase their chances of bringing home the gold. The rationale behind gold productivity from given resources can benefit from quantitative models used to explain Olympic performance. However, it requires the measurement and inclusion of social and psychological variables such as high quality training, heightened concentration, stress management strategies, social support, and others [28].

PLANNING AND ORGANIZING OLYMPIC EVENTS

OR/MS applications to Olympics planning aim at supporting the operation of venues, scheduling of events, information management, and selection of host city (Fig. 3).

Figure 3. Problems in Olympics planning suited to OR/MS application.

OR/MS can help planning, designing, and implementing systems to support venue operations at the Olympic Games, helping the organizing committees to create designs that result in reliable, high-quality venue operations at reasonable cost. The Athens 2004 Olympic Games Organizing Committee (ATHOC) used innovative techniques from MS, systems engineering, and information technology to change the planning, design, and operation of venues [29]. The Process Logistics Advanced Technical Optimization (PLATO) project was developed as a systematic process for planning and designing venue operations by using knowledge modeling and resource management techniques and tools. They developed a rich library of models that is directly transferable to future Olympic organizing committees and other sports-oriented events. The direct financial benefit to ATHOC was the reduction of the costs of managing venue operations by over \$69.7 million. The success of the games raised Greece's international profile in terms of capabilities in managing large and complex projects, in the medium- to long term, with financial, political, and social benefits.

Andreu and Colominas [30] developed a Decision Support System (DSS) to support the scheduling of 2000 events in a 15-day period during the 1992 Olympic Games in Barcelona. The problem is one of multiple criteria; namely, ensure the maximum possible audience for each Olympic event (considering different times and interests across countries); while avoiding inconveniences to athletes, provide an increasing rhythm for the number and quality of finals; ensure that all resources, equipment and personnel are available in due time; and avoid traffic jams. The DSS implementation should satisfy some requirements such as allowing for checking fulfillment of feasibility constraints; adopting criteria categories that make good sense to the end user, instead of easy-to-manipulate from an algorithmic point of view; facilitating the definition, manipulation, examination, and evaluation of alternative schedules according to different criteria as naturally and convenient as possible. The system, called *SUCCESS92* was approved as a useful tool by the organizing committee.

Liao and Chang [31] applied a multiple criteria decision-making method, to help Taiwanese TV companies select optimal televised sportscasters for the 29th Olympic Games held in Beijing, China, from 8 to 24 August 2008. Expert televised sportscasters fully describe, analyze, and comment on the games. The televised sportscaster is a vital contributor to the audiences' appreciation of televised sports. Selection criteria were collected through interviews with 44 executives and televised sportscasters. Twelve criteria that were retained are the following:

Description: Describe the game as it is taking place

Explanation: The ability to analyze. For example: Why implement this tactic?

Expertise: Professional knowledge of sports

Comment: Comment the game, such as the performance of tactics

Order: The ability to finish orders

Cognition: The ability to resolve problem by oneself

Adaptation: Adapt to the external environment

Language: Familiar with foreign languages

Teamwork: Cooperate with others to finish work

Experience: Past experience about sports

Attitude: Conscientious toward work

Response: React appropriately to emergency

Unlike previous contributors who ignored the interdependence among criteria, a more feasible and accurate approach was applied in this article to handle such problems: the analytical Network Process (ANP), which captures the outcome of dependency among the criteria. The ANP extends the Analytical Hierarchic Process (AHP) to deal with dependence. Priorities are established in the same way they are in the AHP, using pair wise comparisons.

Vehicles and pedestrians traffic is a main concern in Olympic Games, given the increased burden imposed on transit

network. Theory of graphs and simulation are some of the OR methods usually applied to support decision making in transportation problems.

During the 1996 Atlanta Olympic Games, the authority deployed an Olympic shuttle bus and a 126 km of high-occupancy vehicle (HOV) lane, expanding rail transit network, to reduce regional commute trips and to alleviate traffic congestion. They also developed the most ambitious intelligent transportation systems (ITS) in the United States [32]. Some impressive results were obtained, concerning reduction of peak flows and increased public transportation volume.

To face the huge Olympic transport challenge, Sydney 2000 established an Olympic Road and Transport Authority (ORTA), a fully multimodal public agency in charge of planning and delivering of all Olympic transport services. According to ORTA's plan, all Olympic stadiums and venues were involved in the public transit system and a new high capacity rail loop with 5.3-km length was built to handle about 80% of the Olympic generated traffic. All measures combined resulted in a background traffic reduction of about 20% and rail traffic growth from 14 to 29.5 million passengers per day.

Transport departments in Beijing worked out "Traffic Assurance Plan during the 2008 Beijing Olympic and Paralympic Games." The general objective was to cut the total number of vehicles on the roads, ensure traffic safety and mobility during the Games, provide public transportation services for citizens to minimize the impact on people's work and daily lives, reduce vehicle emissions, and improve air quality. Liu *et al.* [32] analyzed traffic operation status of different periods, based on surveys and concluded that the successful implementation of traffic control measures during the 29th Beijing Olympics not only promoted the bus-oriented traffic flow composition but also effectively relieved road traffic load.

According to Zhu *et al.* [33], the pedestrian traffic issues aroused by large-scale of people's activities in special events are commonly considered more comprehensive and even cause more serious results than vehicle traffic. As the great demand of spectators

which may induce intermittent walking way, crowded space, and hidden safety problems, it is a crucial process of framing the pedestrian designing and management plan. The pedestrian simulation can be used to assist decision making in the planning phase. The advantages of program simulation are to test the pedestrian facilities and management planning beforehand in order to decrease the probability of potential risks. Usual simulation traffic parameters in train stations, metro stations, and airports are speed and density of pedestrians, which assume particular characters in Olympic events, given the huge centralization in time at a particular site. Zhu *et al.* [33] applied a simulation tool to assess the capacity of facilities, effect, and security of operational planning on different phases of designing and evacuating planning of the National Stadium in Beijing.

Gundlapalli *et al.* [34] report the development of a computer rule-based system that relies on the patient's electronic medical record, transmitted by clinical computing systems and encompassed a variety of types of patient-level data. These includes: laboratory test ordering and results, radiology ordering and reports, emergency room and outpatient clinic visits, and hospital admissions. Several types of rules were developed for this system. Single data source rules were designed to identify occurrences of single important events (e.g., test order for anthrax and test results for influenza). Other rules were focused on specific diagnoses, such as pneumonia by chest radiograph. Groups of rules based on multiple data sources with patient-level data were used as a proxy to identify infectious syndromes. For each rule, statistical process controls were applied to generate alerts when levels exceeded two standard deviations above the mean. The system was deployed at a large hospital in Salt Lake City, during the 2002 Winter Olympic Games, and it was accessed three times a day to perform surveillance. Daily reports were provided to local public health agencies after preliminary investigation of the alerts. Since this system uses objective, quantifiable events, and access to patient data, infection control practitioners could

play a front-line role in biosurveillance and facilitate bidirectional communication with public health agencies [34].

Following the Beijing Olympics, the most important task for the International Olympic Committee (IOC) will be choosing which city hosts the 2016 Summer Olympics. (2012 has already been awarded to London.) The scope of candidacy was narrowed to Madrid, Rio de Janeiro, Tokyo, and Chicago. The winner would be announced in October 2009. How does the IOC make their decision?

While their overall process is popularly described as a two-step process, it is clearly three as mentioned below [35]:

1. Potential cities (not countries) must submit a proposal demonstrating that they meet minimum hosting requirements. These focus on infrastructure, stability, and resources.
2. The 15-member executive board then uses an extensive questionnaire to reduce the list to about 5 to 10 cities.
3. Finally, the full board (currently 115 members) votes. A simple majority (>50%) is required to win. The city with the lowest vote count during each vote is eliminated from the next voting round until a majority is achieved.

According to Ref. 35, “the final phase contains two important flaws. First, the criteria for city selection are relatively loose. While the Olympic Charter provides guidelines and expectations, they lack true criteria, as well as any means to measure the criteria. Board members are left to determine their own criteria and priorities. Second, the voting process focuses on eliminating the least qualified cities rather than valuing the most prepared ones. Through rounds of voting, this process can become more an act of political will than a referendum on the best available option.”

The authors offer an on-line exercise to use a multicriteria model based on six criteria (objectives) and the four finalist cities, to help determine which city should host the Summer Olympics in 2016.

College of Business, University of
Cincinnati, Cincinnati, Ohio

OMEGA RHO

OMEGA RHO INTERNATIONAL HONOR SOCIETY
Operations Research and Management Science

Omega Rho International Honor Society is dedicated to serving students interested in Operations Research and Management Science (ORMS) and primarily does that by honoring students who have achieved sufficiently high grades during their undergraduate or graduate programs. Student inductees are provided with a membership certificate, a piece of Omega Rho jewelry, and a line on their resume that indicates achievement, recognition, involvement, and distinction. Chapters may also induct faculty who are actively involved in teaching or research in ORMS and the executive committee may induct honorary members—persons who have made conspicuous contributions to ORMS. Omega Rho also furthers the discipline of ORMS by sponsoring the *Omega Rho Distinguished Lecture Series*, since 1983 at joint national meetings of the Operations Research Society of America (ORSA) and The Institute of Management Sciences (TIMS), and after their merger in 1995 at the Institute for Operations Research and the Management Sciences (INFORMS) national

meetings. Select INFORMS International Meetings have hosted an *Omega Rho International Distinguished Lecture* since 2001. Omega Rho has consistently cosponsored the ORSA/TIMS/INFORMS Doctoral Colloquium since the 1980s and has supported numerous other ORMS-related student activities since its inception including, for example, travel stipends for students to present at INFORMS meetings, and sponsorship of regional student-centered conferences.

HISTORY AND TRADITIONS OF OMEGA RHO

In 1975, Clint Ancker, Chair of Industrial Engineering at the University of Southern California, lamented the fact that while there were many collegiate honor societies for intellectual achievement, there were none for operations research. With the help and encouragement of Joseph Engel, University of Illinois at Chicago Circle and a Past President (1968) of ORSA, Jack Borsting from the Naval Postgraduate School and President of ORSA during 1975, and others, Omega Rho was founded on April 1, 1976 at the Joint National Meeting of ORSA and TIMS in Philadelphia, Pennsylvania. These 15

*Historian, Website Manager, and Past President. Omega Rho International Honor Society of INFORMS.

universities were the inaugural set of schools to begin inducting members: Case Western Reserve, Clemson, Columbia, George Washington, Illinois-Chicago, Miami University (Ohio), Naval Postgraduate School, New York University, North Carolina State, Maryland, Oregon State, Pittsburgh, Southern California, Southern Methodist, and SUNY Buffalo.

Omega Rho was admitted to the Association of College Honor Societies (ACHS), an organization founded in 1925 to promote high and consistent standards for college and university honor societies, as an Associate Member in 1983 and obtained Full Member status in 1986. ACHS consists of 64 honor societies that are “individually and collaboratively exhibiting excellence in scholarship, service, programs, and governance” [1] and its main goal is to maintain high standards for the recognition and promotion of academic excellence in higher education.

“Ad Optimum per Omega Rho” is the formal public motto for Omega Rho as prescribed in the Constitution. When translated to English, the motto means “Toward the Optimum through Omega Rho.” The official seal is most appropriate for ORMS—a projection of a truncated blue saddle surface with a vertical red arrow centrally located at its base at the bottom of the circle and its head at the saddle point, with the Greek capital letters Ω and ρ in black, and the motto in red.

In October 27, 1998, at the Seattle INFORMS National Meeting, the Omega Rho Executive Committee modified its Constitution, and the INFORMS Board adopted a bylaw, to formally recognize Omega Rho as the Honor Society of INFORMS. Separate meetings for the general membership and the executive committee are held at the INFORMS Annual Meeting each Fall.

Overseeing the Society is the Omega Rho Executive Committee consisting of 15 officers. It is classically structured with a president, vice president/president-elect, secretary, treasurer, historian, two past presidents, and eight regional directors. There are four regional directors for North America (Northeastern, Southeastern, Central, and Western) and one each for Africa, Asia-Pacific, Central and South America, and Europe. Serving as one of these officers

requires two years of valuable service to the ORMS community. An INFORMS liaison is formally designated to work with the Society and the INFORMS Chapter Relations Coordinator currently fills that position. The Executive Committee meets annually at the INFORMS National Meeting, and a General Membership meeting, open to all Omega Rho members, is also held there.

OMEGA RHO MEMBERSHIP IS FOR RECOGNIZING EXCELLENCE

Student participation through one of the 38 established chapters is the life blood of Omega Rho. Chapters are located through universities and have individual constitutions and bylaws. Minimal requirements for membership at the society level are that undergraduate students be in the top 25% of their class and that graduate students have at least a 3.5/4.0 grade point average. However, some chapters have instituted more stringent requirements in their local bylaws. Members may be involved in a wide variety of curricular studies. While an Omega Rho Chapter may be based in a college of business (management science, decision science, quantitative analysis), engineering (industrial/systems engineering, operations research), or science (mathematics, statistics), any ORMS-based curricular study qualifies. The only requirement for student qualification, regardless of major, is success in a significant set of courses in ORMS as deemed satisfactory by the chapter faculty advisor.

If a university does not have a chapter, the Omega Rho Bylaws allow individuals to petition the President for membership. Joining Omega Rho means that a student becomes a member for the remainder of their university career and an alumni member after graduation for life. The one-time cost for joining, US \$20 in 2009, has held steady for at least two decades! A certificate and handsome jewelry depicting a saddle point as in the logo are provided to each member. Honor cords for wearing at graduation ceremonies are also available in blue and red, the official Omega Rho colors.

A faculty performing teaching and/or research in ORMS at an established university chapter qualifies for status as a faculty member. Visitors, such as someone from another university teaching a course or a visitor who is doing research with faculty or students while on a sabbatical leave, also qualify for induction by a local chapter. Upon leaving the university, faculty members also become alumni members of the local chapter. Approximately 6100 students and faculty have been inducted through 2009. The membership directory on the INFORMS website now lists Omega Rho members through their initiating chapter.

Honorary member status is only awarded to exceptional individuals in ORMS and must be approved by the executive committee. Primarily, this status is employed to honor the presenter of the *Omega Rho Distinguished Lecture* and *Omega Rho International Distinguished Lecture* but has also been occasionally used by local chapters to honor worthy visitors and speakers. Through 2009, 43 honorary members have been inducted into Omega Rho.

THE OMEGA RHO DISTINGUISHED LECTURE SERIES

“To recognize academic excellence”—a part of the Oath for Omega Rho—has been extended to significantly recognize the best in research and application through the *Omega Rho Distinguished Lecture Series*, arguably one of the most prominent series of lectures on ORMS in the world. Recognized as an “Area of Excellence” by ACHS [2], the distinguished lecture has been a plenary presentation at ORSA/TIMS/INFORMS meetings since Russell L. Ackoff delivered the first such lecture on November 8, 1983, at the ORSA/TIMS Orlando, Florida, meeting. Other notable distinguished lecturers have included George Dantzig, Nobelist Herbert A. Simon, Alan B. Pritsker, and a host of contemporary honorees, all in a series of presentations of unsurpassed quality in ORMS research and practice. *Omega Rho Distinguished Lectures* have addressed a wide variety of novel topics in such important areas as health-care delivery, airline

safety, public sector issues, e-commerce, service management, and manufacturing simulation, while other lectures were on the more traditional topics of queueing, linear programming, and artificial intelligence. Some of the more provocative talks in the series dealt with evaluating life and death decisions, resurrecting the economy, resizing the federal government, ethical and social responsibility issues in ORMS, human genome sequencing, and HIV prevention.

The *Omega Rho International Distinguished Lecture* has been delivered at four select INFORMS International Meetings. William R. Pulleyblank presented the first such lecture during the Society’s 25th anniversary at the INFORMS International Meeting in Hawaii in 2001. A total of 35 *Distinguished Lectures* and *International Distinguished Lectures* have been presented through 2009. Complete details for each lecture are available at the Omega Rho website, OmegaRho.INFORMS.org.

SERVICE FOR OMEGA RHO IS REWARDING

Service for an honor society is student-oriented, consistent with the educational goals of most university settings, and usually regarded as a worthy activity by department chairs, deans, and provosts. Working with Omega Rho is gratifying from many perspectives:

- Faculty work to honor and serve the best students and promote academic excellence with the ORMS community at large.
- Omega Rho promotes and sponsors activities to showcase the best of ORMS.
- Omega Rho provides service to the ORMS profession with support of the INFORMS doctoral colloquium and other student-based activities.
- Omega Rho helps spread the idea of the value of ORMS to the outside community and the value of “The Science of Better.”

Further credit comes to those who serve Omega Rho as president. The post

involves an eight-year commitment—two years as president, two prior years as vice president/president-elect, and a subsequent four-year term as past president and executive committee member. Often, the president has already served as secretary,

treasurer, historian, regional director, and/or a faculty advisor. Omega Rho has been fortunate to have had the following talented, hard-working senior faculty serve as President:

Clinton J. Ancker, Jr.	University of Southern California	1976–1978
Joseph H. Engel	University of Illinois at Chicago Circle	1978–1980
Burton V. Dean	Case Western Reserve University	1980–1982
E. Leonard Arnoff	University of Cincinnati	1982–1984
Dundar F. Kocaoglu	Portland State University	1984–1986
Saul I. Gass	University of Maryland	1986–1988
Paul Gray	Claremont Graduate University	1988–1990
A. Ravindran	University of Oklahoma	1990–1992
Mary W. Cooper	Southern Illinois University	1992–1994
U. Narayan Bhat	Southern Methodist University	1994–1996
Bruce W. Schmeiser	Purdue University	1996–1998
David F. Rogers	University of Cincinnati	1998–2000
Richard M. Soland	George Washington University	2000–2002
Yupo Chan	University of Arkansas at Little Rock	2002–2004
George G. Polak	Wright State University	2004–2005
Subhash C. Narula	Virginia Commonwealth University	2005–2008
Christopher M. Rump	Bowling Green State University	2008–2010
James K. Lowe	United States Air Force Academy	2010–2012

At the 75th anniversary celebration of the ACHS held on February 19, 2000, each honor society recognized “five persons who have contributed to the well-being of the Society.” The five recognized for Omega Rho were all former presidents:

- Clinton Ancker and Joe Engel, the first presidents and driving forces behind founding Omega Rho and making it operational.
- Richard Soland, who served as long-time executive director and treasurer and was key in maintaining and enhancing Omega Rho’s presence through the 1980s and 1990s.
- Saul Gass, involved in creating Omega Rho and in all the years since then recognized for consistently serving Omega Rho on many committees including the Bylaws Revision Committee.

- David Rogers, who expanded the presence of Omega Rho through new chapters, chaired the 1998 Bylaws Revision Committee, spearheaded Omega Rho becoming a part of INFORMS, and developed and maintained the extensive archival internet website for the society.

OMEGA RHO LOOKS TO THE FUTURE

Omega Rho has a ceaseless desire to first and foremost serve and recognize students, faculty, and professionals of ORMS. We are also relentless in our efforts to help spread awareness of the value of the profession. An ongoing activity is promoting growth by establishing new chapters and the Omega Rho website has information and documents to assist with this endeavor. The *Omega Rho Distinguished Lectures Series*, sponsorships

for the INFORMS Doctoral Colloquium, and other student-oriented activities will likely remain a constant of Omega Rho activities. As the world has grown smaller with virtual connections, as honor societies become more typical in universities where they have not previously existed, and as ORMS spreads to developing nations, Omega Rho will continue to increase its chapters worldwide to include recognition for deserving individuals around the globe.

More information about Omega Rho can be accessed from its website at OmegaRho.INFORMS.org or through the INFORMS website, www.INFORMS.org under "Communities." There one can find current and archival information including the constitution and bylaws, oath, current and past officers, chapter locations, meeting minutes, honorary members, the *Distinguished Lecture Series*, upcoming meetings, and assistance for starting a new chapter.

Acknowledgments

Past Omega Rho Presidents Paul Gray, Richard Soland, and Yupo Chan are gratefully recognized for their editorial inputs. Artwork in this article is the property of Omega Rho International Honor Society.

“ON-THE-SPOT” MODELING AND ANALYSIS: THE FACILITATED MODELING APPROACH

LUIS A. FRANCO

APPROACHES TO MODEL-BASED CONSULTANCY

The most common approach to undertaking model-based consultancy in management science has been what is known as the *expert modeling* mode, where the management scientist uses powerful quantitative methods and models that enable an “objective” analysis of the client’s problem situation, together with the recommendation of optimal (or quasi-optimal) solutions to alleviate that problem situation. Most management science textbooks offer excellent advice on how to deploy the expert mode of model-based consultancy, which has been successfully used to solve a broad range of challenging management problems in areas such as logistics, operations, marketing, and finance. This is aptly illustrated by the EURO Medal and the Franz Edelman prizes, two of the most prestigious awards for the practice and proven impact of management science and operational research projects.

Broadly speaking, we can identify four tenets underlying the expert modeling mode of model-based consultancy. First, the expert modeling mode assumes that the problem situation to be addressed by the consultant exists as an external reality, and therefore its actual definition and scope should not depend on which stakeholder is describing

such reality. Indeed, the task of the consultant is to remove any “bias” in the description of the problem in order to solve the “real problem” [1]. This obviously has an impact on how problems are framed and formulated. In particular, it means that it is the task of the consultant alone to frame “correctly” the problem and formulate “precisely” the model, without the need of major client involvement in the modeling process.

Second, model-based analysis in the expert mode should be objective, and thus individual opinions and different views about the problem should be at least suspended and at best avoided [2]. This leads consultants to define, by themselves, the metrics that they will be using for evaluating solutions, based on prior categorizations of problems and how these are typically solved. It also means that analysis will be based mostly on “hard” quantitative data and conducted in the backroom, as modeling and analysis is likely to be technically challenging.

The expert modeling mode also assumes that clients hire consultants for their expertise in providing optimal (or quasi-optimal) solutions to problems [2]. This is usually communicated via a detailed report that contains the optimal recommendations as well as a summary of the main assumption(s) employed in the analysis. Finally, there is an expectation among expert consultants that the implementation of solutions derived from well-conducted model-based analysis will be relatively straightforward. As the solutions proposed are clearly optimal, there is little reason why they should not be implemented by the client who commissioned the analysis [3,4].

The expert modeling mode has proven to be a natural and sensible way to solving complex operational or recurrent problems in organizations. On the other hand, when dealing with problem situations at a more strategic or policy level, the expert mode of consultancy may not always be appropriate for several reasons. First, strategic or policy

issues typically generate competing hypotheses about the scope and depth of the problem situation to be tackled, which will make its definition a contested process for the organization's stakeholders. In addition, the distinct and, often conflictive, objectives, values, and interests of the stakeholders will have to be accommodated before and during the analysis, in order to reach a “working consensus” about the way forward. Finally, such situations pose a substantial challenge to both clients and consultants regarding decisions about the appropriate level of participation in the problem solving process, which will have a substantial impact on whether the solutions derived from the analysis are both desirable for the stakeholders, and politically feasible (i.e., implementable and supportable) for the organizational units they represent [5,6].

For problem situations such as those described above, an alternative mode of model-based consultancy, known as the *facilitated modeling* mode has been developed [7]. In this mode a team is drawn from the client organization (or sometimes more than one organization with a stake in the problem) and is typically placed as responsible for scoping, analyzing, and solving the problem situation of interest; the team is supported by the consultant, who acts both as an analyst and as a facilitator. Every step taken in the intervention—from defining what the problem really is, to creating and analyzing models, and providing the recommendations—is conducted interactively with the team. This produces noticeable differences in the way the consultancy engagement is undertaken, as we discuss next.

The facilitated modeling mode recognizes that, while some aspects of problems are tangible, their nature and salience will depend on how stakeholders subjectively construct them. Different stakeholders will perceive the same problem situation in quite diverse ways, influenced by their distinct interests and organizational roles and, therefore, will describe the situation according to those perceptions. Instead of trying to define the “real” problem, the consultant in this mode will support the team to come up with a joint problem definition, which encompasses the

main features of their individual perceptions about the situation [1,3,8].

In addition, the facilitated modeling mode acknowledges that problem situations always involve subjective elements; for example, different perceptions about the desired future of the organization, distinct opinions about what or which organizational objectives to pursue, and the presence of organizational objectives that are of a qualitative nature [4,5,9]. Instead of disregarding such aspects as “nonrational” or irrelevant, the consultant operating under the facilitated modeling paradigm helps the team to externalize such subjective issues and represent them in formal models.

The facilitated modeling mode also assumes that results from model-based analysis are considered by clients as a mere indication of what would happen if the solution were implemented. The view among facilitated modeling consultants is that clients are usually satisfied in finding a set of good options that can provide clear improvements to the organizational system, and which are deemed implementable at the same time [10,11].

Finally, a major tenet of the facilitated modeling mode is that the involvement of the key stakeholders in the process of modeling and analysis markedly increases the chance that recommendations of the analysis will actually be implemented [5,6,12–14]. The underlying rationale is that their involvement will make stakeholders more confident in the analysis performed, and more committed to the recommendations derived from it. Such confidence and commitment will be strengthened if: key stakeholders believe that their views, preferences, and objectives are taken into account; the model represents adequately the problem they want to tackle; the modeling assumptions are organizationally realistic; and the solutions derived from the analysis are sound and justifiable.

In summary, two alternative models of model-based consultancy are available to the management scientist: expert and facilitated modeling. Neither of these modes is necessarily superior. For complex operational problems, the expert modeling mode is usually quite appropriate: there is a clear and unarguable quantitative objective to be

optimized; the structure of the problem is well-known and renders itself to quantitative modeling; and solutions are clear-cut and easily implementable. On the other hand, strategic and policy issues and high-stake decisions are likely to require a facilitated modeling approach due to their complex quantitative and qualitative dimensions, and the need to engage a team of stakeholders in the problem solving process [5,11,15,16].

The rest of the article is structured as follows. In the next section we discuss four key dimensions of facilitated modeling: the characteristics of the modeling process; the nature of the models produced; facilitated modeling outcomes; and facilitation issues. We then briefly review several well-established facilitated modeling approaches developed within the operational research, decision sciences, and systems fields. In the latter part of the article we examine some of the key design choices open to the consultant interested in applying facilitated modeling in practice. We end the article with conclusions and suggest possible directions for future work in the field of facilitated modeling.

WHAT IS FACILITATED MODELING?

We use the term *facilitated modeling* to describe a process by which formal models are jointly developed with a group of stakeholders, with or without the assistance of computer support, and in which insights about the problem situation being modeled is the result from model-based analysis produced “on-the-spot” [7,16–18]. We consider a model as “formal” if it represents a problem situation in any of the following ways: (i) activity or process flows; (ii) cause and effect relationships; or (iii) relationships between decision choices and their (deterministic or uncertain) consequences. A formal model is amenable to analysis and manipulation, but not necessarily quantifiable. Models produced in the facilitated modeling mode are “transitional objects” [17,19] used by stakeholders to share and increase their individual understandings of the problem situation of interest, appreciate the potential impact of different options, and negotiate courses of action that are politically feasible.

In facilitated modeling, the consultant must use facilitation to support the modeling process. Model-based facilitation, however, is different from the type of group facilitation that is commonly used in the organizational development field [20,21]. Although both forms of facilitation are similar in the way the consultant provides process support to a group, it is the handling of the content of group members’ communicative exchanges where the main difference lies. In facilitated modeling, content is managed through the use of formal models, as opposed to other facilitative means. Modeling and model use is the defining characteristic of facilitated modeling, and what gives it its unambiguous management science identity.

Figure 1 captures the main aspects of facilitated modeling. The figure suggests that the consultant interacts simultaneously in two “spaces”: as an analyst in the *modeling space* and as a facilitator in the *group process space*. In the former, the consultant uses a particular management science methodology to build a model that is a representation of the problem situation as described by the group. Meanwhile, in the *group process space*, the consultant facilitates the group (informed by facilitation methods and tools), supports the group’s discussion and interacts with the group’s members. The group provides information that enables the consultant to model the problem situation of concern and, conversely, the model generates responses that inform the group’s discussions about the situation. Two types of outcomes are provided by facilitated modeling: in the modeling space, there are *model outcomes* (such as priorities for actions, system’s responses, etc.); in the group process space, there are *group outcomes* (such as commitment to action, learning, etc.). The two spaces cannot be divorced from each other [22], as there will be cross-impacts from one space to the other (for example, conceptual mistakes in the model may generate meaningless system’s responses, which then impact negatively on group outcomes, such as creating low commitment to action).

In the section below, we examine the notion of facilitated modeling in more detail.

Figure 1. The facilitated modeling process (Source: Based on Franco and Montibeller [7]).

Our discussion will be organized around four key aspects of facilitated modeling: process, models, outcomes, and facilitation skills.

The Process of Facilitated Modeling

The primary orientation of facilitated modeling is to assist a group of stakeholders in agreeing with the nature of a problem situation of concern, and on a feasible action plan intended to tackle that situation so that progress can be made. This is because, when dealing with situations involving strategic problems, complex policy issues, or high-stake decisions, there is likely to be a plurality of stakeholders with different interests who will need to engage in a dialogue if the problems they face are to be resolved by means other than an overt exercise of power [5].

Consequently, facilitated modeling can be thought of as a conversational process [23] in which stakeholders take part to exchange their understandings and views about the situation that is being analyzed. This process is thus a participative one, in the sense that stakeholders are able to jointly construct the situation, make sense of it, arrive at a shared problem definition, and develop and evaluate a portfolio of options relevant to the problem so defined. This participatory process is

supported by the consultant acting both as a modeler and a facilitator [24,25].

Because interaction between the stakeholders, and of the stakeholders with the analysis, is needed to jointly build a model of the problem situation, facilitated modeling is also an interactive process. Stakeholders' interaction with the model reshapes the analysis, and the model analysis reshapes the group discussion. Such interactive processes continue until the problem situation is satisfactorily structured and analyzed, so that the group feels sufficiently confident in making commitments and implementing options.

Facilitated modeling is typically organized into group work stages that roughly correspond to: structuring the situation and agreeing on a problem focus; developing a model of organizational objectives or systems; creating, refining, and evaluating options for action; and, developing implementation plans. This “staged-ness” makes it possible for stakeholders to end the process without passing through all the stages, and still have a tangible product that can be of use to them. Furthermore, the stages of facilitated modeling do not have to be followed in a linear sequence; rather, it is possible for the participants to cycle between the stages.

A characteristic feature of facilitated modeling is its ability to enable stakeholders, during the modeling process, to distance themselves from previous bindings, effectively providing them with a certain degree of detachment regarding their own stakes [11,17]. This, it is argued, allows stakeholders to change their initial positions in response to what they have learned about the problem situation without destroying the social order in the group [17]. Changing positions imply stakeholders “changing their minds,” that is, changed beliefs, changed values, and changes in the salience of particular issues or values [26]. The consequence of these changes is that it becomes easier for participants to reconcile the position they eventually take both with principles and with past words and actions during the modeling process.

Thus far we have looked at the characteristics of a facilitated modeling process. As we have seen, facilitated modeling requires a consultant supporting a group model-building process that must be participatory, interactive, staged, and nonlinear, and one that enables stakeholders a certain degree of detachment from their stakes in order to make change possible. At the same time, the consultant must be responsive to the dynamics of group work and the particularities of the situation at hand.

In terms of technology, facilitated modeling can be a relatively unsophisticated activity, typically conducted in a workshop format, and one which does not necessarily require software to support it [27]. Noncomputer-supported environments typically involve [28–30]: a room spacious enough for participants to move around freely and with movable chairs laid out in a horse-shoe fashion; large sheets of paper attached around the walls of the room; a simple, nonpermanent means of sticking papers to these walls (e.g., blu-tack); and a good supply of marker pens with contrasting colors. Facilitated modeling can also be deployed with computer support. In this case, specialized software is used to support the processes [17,31,32]. This kind of software enables fast model building and real-time computing [17,27]. Some software, such as *Group Explorer* (www.banxia.com) and *VISA groupware*

(<http://www.simul8.com/products/visagroup.htm>), also allows participants to enter their views relating to a problem situation directly and anonymously into it. The system is then operated by the consultant who manipulates and analyzes the data according to the requirements of the group or the task. Once a model of the problem is built and stored in the system, several analyses can be performed “on-the-spot.” Figure 2 illustrates both computer and noncomputer-supported modeling environments.

The Nature of Models in Facilitated Modeling

As stated earlier, models produced in facilitated modeling interventions provide stakeholders with a facilitative device or transitional object [17,19], that is, a “play tool” that allows them to rehearse ideas and action possibilities about the situation of interest [18]. The availability of such a tool, it is argued, increases stakeholders’ multiple understandings of the problem situation, and supports them in negotiating courses of action that are desirable and feasible for the stakeholders.

The models resulting from facilitated modeling represent, among other things, relationships between concepts, activities, or stakeholders; relationships of similarity or influence; and relationships between options. The particular elements contained in any model will depend on the focus of the model (e.g., choices of options, design of systems) and on the group task they mainly support (i.e., problem structuring, decision making, or both).

It has been claimed that visual methods are of particular value in representing complexity to lay audiences who might otherwise find quantitative models opaque [5,11]. For a model to be considered a useful and legitimate facilitative device by stakeholders, it should be open (i.e., nothing is hidden), transparent (i.e., easy to understand), and accessible (i.e., simple to use). Thus, “facilitative models” are essentially visual displays (e.g., cognitive and causal maps, causal loop diagrams, decision graphs, value trees) containing the stakeholders’ own language used to describe the problem situation of concern,

Figure 2. Computer- and noncomputer-supported environments in facilitated modeling.

together with their own judgmental preferences implied by different decision options.

A consequence of considering a model as a facilitative mechanism is the challenge of assessing what constitutes a valid model and a good model solution. Probably the best answer to this issue is to employ the concept of “requisite-ness” [10]: a model is requisite if it contains sufficient knowledge and information to help the stakeholders find a way forward about the problem situation of concern.

The Outcomes of Facilitated Modeling

A number of outcomes have been claimed to be the result of the use of facilitated modeling approaches. Some of them will be tangible outputs of the modeling process itself, while others will be less visible but valuable in their own right.

The most visible facilitated modeling outcome is obviously “the model” object that is built during the process. The model contains the structure of the problem situation, and allows performing on-the-spot analyses and drawing conclusions from its responses. Furthermore, the model is thought to facilitate the achievement of a number of invisible outcomes, of which we will cite three considered central. First, it is argued that by allowing the mutual exploration of the problem structure as portrayed by the model, facilitated modeling enables the accommodation of multiple and differing positions among stakeholders [33]. This argument is based on the notion that strategic problems, policy issues, or high-stake decisions will commonly

require stakeholders to adjust their positions and/or expectations to take into consideration the possible objectives and interests of others [5]. Accommodations between stakeholders may also require coalition forming [26,34], which can produce a shift in power relations between the stakeholders participating in the modeling process [17].

Second, the analysis and manipulation of the relationships between model variables, together with the evaluation of decision options, is thought to give stakeholders an increased and shared understanding (rather than full consensus) of the problem situation, of the impact of potential courses of action, of others’ beliefs and values, and of organizational roles, processes and cultures [5]. Such gained understanding is taken to be conducive to developing a sense of common purpose that preserves individual differences of opinion among stakeholders [13,35], as well as learning [6,14,36,37].

Finally, it is argued that stakeholders’ active participation in modeling and analysis produces strong ownership of the problem formulation as well as a commitment to the way forward, in the sense of an acceptance of joint responsibility for the consequences of the actions taken [5,6,13].

Facilitation Issues

As already stated, facilitated modeling requires the consultant to act both as an analyst and as a facilitator during the modeling process. This means that the consultant should be not only proficient in the particular

modeling approach to be deployed with the group, but also adept in group facilitation to support the modeling work. A comprehensive discussion of the general skills and competences required to facilitate groups is beyond the scope of this article, and the interested reader is invited to consult the mainstream facilitation literature [20,38,39]. In the discussion below, we consider issues specific to facilitating groups within the context of modeling, drawing mainly upon the seminal work of Phillips and Phillips [24].

It is argued that when a group gets together to perform a task, the group acquires a character or a personality while working on the task. The group also has an emotional life that develops and changes over time, sometimes in abrupt and unpredictable ways, which can substantially affect the effectiveness with which the members of the group carry out their task [40].

While group life can affect the individuals in a group, so also each individual can affect the group. The individuals and the group mutually interact and influence each other and can be thought of as a “system.” Furthermore, tensions within this system can arise because of the interplay between individuals and the group. These tensions are the main source of conflict in the group, as well as the anxiety and even frustration commonly experienced by group members. If such conflict, anxiety or frustration are not acknowledged, tolerated, and held by group members, they may be dealt with it in non-effective ways. For example, group members may project it onto other group members or the facilitator; group members may form coalitions or become dependent on the facilitator [40]; or group members may avoid and table conflict altogether to maintain the cohesion of the group, a typical manifestation of “group thinking” [41] and “group centrism” [42]. These coping strategies reduce conflict, anxiety, or frustration by diverting the group from the task at hand.

Although the group life works its effect through the group members, it is often the case that they do not see it because their attention is focused on the task. The consultant must therefore be able to recognize and understand the effect of the group life

on the performance of the group task. This can be achieved in three main ways [24]: by observing group roles and relationships, by attending to symbolic content in the group discussion, and by monitoring feelings (the group’s as well as the consultant’s). Understanding the group life is, however, not sufficient. The consultant must also intervene when appropriate in order to help the group carry out their task more effectively. Without giving advice, providing evaluation or interpretation, or contributing to content, the consultant can intervene in at least four different ways [24]: by pacing the task against progress; by directing the group about work steps; by reflecting back content or handing it back in changed form to provide a new perspective; and by questioning and summarizing to increase understanding. The interested reader is referred to Phillips and Phillips [24] and Ackermann [25] for a more detailed discussion of observation and intervention strategies available to the facilitated modeling consultant.

Before we discuss choices related to the design of facilitated modeling interventions, we offer next a brief review of some of the more established facilitated modeling approaches.

BRIEF SUMMARY OF FACILITATED MODELING APPROACHES

We will attempt here to very briefly summarize a number of well-established facilitated modeling approaches within management science. We have selected a family of approaches that, in our view, sit comfortably within the definition and characteristics articulated above. We classify them in three groups according to the general modeling methodologies from which they are derived (in alphabetical order): decision analysis, problem structuring methods, and system dynamics.

Facilitated Decision Analysis

The combined use of decision analysis methods, group facilitation, and computer-supported modeling led to the development of a facilitated modeling approach known

as *decision conferencing* in the late 1970s [32,43,44]. During a decision conference, computer-based models are used as a focus for group discussion and the structured group process allows participants to debate issues constructively while forcing them to represent their collective judgments in a logically consistent and easily communicated fashion. Although supporting information is important, it is the substantive expertise of the participants that is key to the success of decision conferences. For further details, see Phillips [13].

Facilitated Problem Structuring

A set of methods originated mainly within the British operational research community in the late 1970s and early 1980s. Their main features are the assumption of subjectivism (different views about the world); the significance of problem formulation and definition in facilitating joint agreements and coordinated action; and the limited role of quantification in the analysis of problem situations (mostly qualitative modeling). Well-established problem structuring methods include strategic options development and analysis (SODA) [34,45], journey making [6], strategic choice approach [12], value focused thinking [9], and dialogue mapping [46]. For further details, see Rosenhead and Mingers [5] and Jackson [47].

Facilitated System Dynamics

Since the late 1980s, the system dynamics community has made considerable progress in developing tools and techniques to support a facilitated modeling process. The result has been an approach known as *group model building* [48–51], which employs a mixture of system dynamics modeling techniques, such as causal loop diagrams, stock and flows diagrams, and graphical functions, in combination with guidelines for facilitating group sessions to foster organizational learning and change [52–54]. The interested reader is directed to Vennix [14] for further details.

Facilitated modeling has been applied in a wide variety of areas including health [55–60]; transport [61,62]; natural

resource management [63–66]; manufacturing [67,68]; project management [69–71]; knowledge management [72,73]; strategy development [74–78]; information systems [79–81]; interorganizational collaboration [82,83]; community work [84–87]; portfolio analysis [88–90]; and project prioritization [91]. It is worth noting that, although we have presented the above families of facilitated modeling as separate entities, an increasing trend observed in practice combines or integrates different facilitated modeling approaches to create novel “multimethodology” designs [92] that aim to take benefit from their strengths—for recent multimethodology applications of facilitated modeling, see Bana e Costa [91], Andersen [93], Franco and Lord [94], and Montibeller [95].

DESIGN CHOICES IN FACILITATED MODELING

In this section we focus on design choices that the consultant may consider when conducting interventions based on facilitated modeling. Our emphasis will be on the design of the facilitated modeling process itself, rather than the entire intervention. Broader design issues related to facilitated modeling interventions, including the management of the consultant–client relationship, have already been treated extensively elsewhere [4,24,25,34,96], and the interested reader is referred to these works.

The focus of our discussion here will be on a single facilitated modeling session delivered in a one- to three-day workshop format, which is the typical format adopted by many facilitated modeling approaches. We have identified six dimensions as key when designing such a session: modeling focus, data collection strategy, data requirements, technology support, flexibility of modeling rules, and content facilitation requirements. Each of these are discussed next.

The first dimension is the *modeling focus*, as a facilitated modeling session can be designed mainly to support problem structuring or the evaluation of options. Problem structuring is typically supported via problem structuring methods such as SODA

or the strategic choice approach, whereas approaches such as group model building and decision conferencing have been used mostly to support the quantitative evaluation of options. Different modeling skills are required for each phase; for example, problem structuring requires the modeler to cope well with ambiguity, multiple perspectives, and a large amount of qualitative data; while the evaluation of options requires a modeler with synthesizing abilities and the ability to handle a large amount of quantitative data. Supporting both activities, within a single intervention, is also feasible, but it requires the consultant to be able to adopt a multi-methodology approach intervention [92,97].

The second dimension concerns the *data collection strategy*. Some facilitated modeling approaches use well-defined categories to elicit data up front, as in the case of, for example, the strategic choice approach (e.g., decision areas, uncertainty areas, comparison areas) [12]. Other approaches involve eliciting all relevant data before predefined categories are applied to it. This form of data elicitation is typical of approaches such as, for example, SODA, group model building, and dialogue mapping. Different data elicitation approaches pose different demands on how the consultant manages the content of the model: the first approach requires working inductively, whereas a deductive way is required for the second one. The choice of approach will thus depend on the particular preferences of the consultant working either inductively or deductively, as well as on the stakeholder group's adaptability in providing the data in the elicitation formats required by the modeling approach adopted.

A related issue, and the third dimension, is the type of *data requirements* for building the model. Some models are mainly diagrammatic representations of the problem situation and thus have reduced quantitative data requirements (e.g., a cognitive map or a causal loop diagram), closer to the way stakeholders think and communicate. Others, such as a decision analysis model require data in quantified form (even if only judgmental data is available) in order to build the model. The degree of quantification needed for some facilitated modeling approaches thus, requires

the consultant to be aware of the cognitive demands that this may impose on the group. For example, research has shown that quantitative judgmental data can be difficult to elicit [98] and influenced by cognitive biases [99–101]. On the other hand, quantitative models tend to produce outputs that are less ambiguous and more amenable to further analysis. Therefore, the consultant needs to make a choice between these two conflicting modeling objectives, given the type of problem situation that the stakeholder group wishes to address and the background of those participating in the modeling process.

The amount of data elicited (whether qualitative or quantitative) in facilitated modeling sessions is usually high, which can challenge participants' information processing capabilities [102,103]. This raises our fourth dimension, the *degree of technology support* needed for a facilitated modeling session (where the term *technology* is used to describe the level of computer support used in the session). Problem structuring methods such as the strategic choice approach, for example, have traditionally favored unsophisticated forms of technology support (i.e., manual rather than computer-based). On the other hand, approaches within which models are built to perform numerical calculations and/or quantitative sensitivity analyses, such as decision conferencing or group model building, tend to rely almost exclusively on computer support [32], which can be used in “single-user” mode (facilitator operates the modeling software) or multiple-user mode (participants are able to use the modeling software themselves guided by the facilitator) [104]. Other modeling approaches such as SODA tend to use a combination of both computer and noncomputer support.

A decision about which level of technology support is appropriate for a facilitated modeling session will depend on several factors. First, the consultant's personal preferences for the use of technology are an obvious influence, as well as the perceived complexity associated with the modeling task. As stated earlier, facilitated modeling requires “on-the-spot” modeling and analysis of a large amount of data. A noncomputer-supported environment will restrict the speed at which

the data is elicited and manipulated, making the task relatively easier for both the consultant and the participants. On the other hand, computer-supported environments may be more effective in terms of collecting large amounts of data in less time (particularly those that allow a multiuser mode of working), but they can pose considerable challenges to the modeler's ability to structure the data, as well as to the participants' understanding of what is going on, due to the speed at which data is elicited and structured. Consequently, when the different levels of computer technology are being considered, having more than one facilitator/modeler for the session may be needed [31].

The fifth dimension is the *degree of flexibility of the modeling rules* being employed. Some methodologies underlying particular facilitated modeling approaches, such as decision analysis (for decision conferencing) and system dynamics (for group model building), require stricter specification of variables and the fulfilment of a larger number of structural properties. On the other hand, facilitated modeling approaches such as SODA are usually more flexible in their modeling rules. Stricter rules usually permit a higher level of inference in the model, particularly important when appraising alternatives and policies. Conversely, the flexibility is beneficial for representing problem situations where there is high ambiguity of meanings and multiple perspectives, and common features of the modeling context in which problem structuring methods operate. Furthermore, some problems may require different levels of formal analysis and interaction with the group (for instance, from representing the problem with a qualitative model to evaluating quantitatively options). Such features then guide the choice about the degree of flexibility of its modeling rules required and, consequently, the choice of the method to be employed in the intervention.

The final dimension we suggest is the *degree of content facilitation* required in a modeling session. Some modeling approaches require strong content facilitation as in the case of SODA, decision conferencing, and group model building, where more than one facilitator/modeler for the session may be

advisable or even necessary [31]. On the other hand, approaches such as the strategic choice approach can allow a group to become self-facilitated after the modeling guidelines of the approach have been internalized by the participants. This means that a less central role may be required for the consultant, who will only have to ensure that the modeling guidelines are being followed throughout the process. In addition, allowing groups to self-facilitate themselves for certain tasks within the modeling session can help to keep up the momentum, and energy levels, within the group. On the other hand, it does require that the group is self-motivated and competent enough to perform the modeling tasks that the consultant asks them to carry out.

The six dimensions we discussed above are somehow idiosyncratic, as they are drawn from our particular experiences as academic practitioners of facilitated modeling. Nevertheless, our aim has been to provide some useful insights into the design choices open to the consultant interested in applying facilitated modeling. In Table 1 we present a summary of each dimension, with its description, range, and some implications for practice.

CONCLUSIONS AND DIRECTIONS FOR FUTURE RESEARCH

This article reviewed a particular mode of model-based intervention in organizations: facilitated modeling—a process by which models are created jointly with a stakeholder group within a facilitation paradigm. Our discussion distinguished the facilitated modeling mode of intervention from the expert modeling approach typically adopted by consultants within the management science domain. We advanced a definition for facilitated modeling, and discussed several of its main aspects such as process, models, outcomes, and facilitation issues. We also proposed a classification of facilitated modeling approaches, based on the modeling methodologies from which they have been developed, and a set of choice dimensions that may be relevant when designing facilitated modeling interventions. Finally, we noted that facilitated modeling demands a particular set of skills

Table 1. Design Choices in Facilitated Modeling (based on Franco and Montibeller [7])

Dimension	Description		Range		Choice Influenced by:
Modeling focus	The extent to which the approach provides support to a particular phase of decision making	Emphasis on problem structuring	↔	Emphasis on the evaluation of options	- Facilitation skills of the consultant - Type of problem to be tackled
Data collection strategy	The way in which the data about the problem is gathered and employed to structure the model	Inductive (categories are created from data)	↔	Deductive (data is elicited for predefined categories)	- The consultant's preferences for working inductively or deductively with data - The adaptability of participants to provide the data required by the model
Data requirements	The type of data required by the model	Data of qualitative nature	↔	Data of quantitative nature	- Type of problem to be tackled - Balance between ambiguity and precision - Participants' background
11 Technology support	The degree of technology support required by the modeling approach	Manual	↔	Computer-supported (single-user or multiuser)	- Personal preferences of the consultant - Acceptable levels of risk for modeling "on-the-spot" at different speeds - Availability of more than one facilitator
Flexibility of modeling rules	How flexible are the modeling rules required by the methodology being employed	Flexible	↔	Strict	- Phase of the decision making being supported - Type of problem to be tackled - Type of analysis required
Content facilitation required	The degree of content facilitation required by the modeling process	Self-facilitation by the group	↔	Strong facilitation by the consultant	- Demands placed on the consultant - Need for keeping momentum and energy levels in the group - Degree of self-motivation and competency of participant

on the part of the consultant. Although these challenges have been discussed in separate management science subfields (e.g., decision analysis, problem structuring methods, system dynamics), we attempted in this article to provide a unifying framework that could allow us to increase our understanding of different forms of facilitated modeling.

Another aspect that is relevant to be highlighted is that, in our view, there is not a “best” mode of organizational intervention (facilitative vs expert mode): such choice has to be made based on the nature of the problem situation that the consultant is dealing with, as well as the consultant’s own preferences. This is in contrast to suggestions that one is better than the other, or that there is one “right” approach to intervention. Nevertheless, we should say that, from our practical experience, the facilitative modeling approach is particularly suitable for supporting organizational problem structuring and/or strategic decision making given its socio-technical complexities.

Several areas for further research can be envisaged, and we suggest some of them below.

- *Better understanding of facilitated modeling processes in practice.* Most of the evidence about the use of facilitative modeling in practice has tended to be purely anecdotal. There have been recent attempts to conducting research on this topic using more systematic observation and analysis [72,105,106], and much could be learnt with more extensive research programs in this area.
- *Generalization of best model-based facilitation practices:* Following from the previous item, a better understanding of facilitated modeling practices could (and should) be focused on trying to generalize best model-based facilitation. We feel that just importing the literature of standard facilitation is not always viable, as facilitated modeling is a complex endeavor requiring a variety of skills and behaviors. Although there is some evidence of work in this area

[25,107,108], there is still considerable scope for further work.

- *Systematic assessment of outcomes from facilitated modeling interventions.* Most of the literature on facilitated modeling makes bold claims on the outcomes that it provides, as reviewed in this article. However, the number of studies that tried to systematically assess such outcomes is quite limited [35,109,110,111]. There is thus wide scope for further studies in this area, both in the laboratory and the field.
- *Test the validity of design dimensions for facilitated interventions.* This article suggested a set of dimensions that, in our view, should be considered when designing a facilitated modeling intervention. It would be interesting to conduct empirical research to test the validity of such dimensions.
- *Increase the family of facilitated modeling approaches in management science.* Most facilitated modeling approaches were developed by adapting a mainstream management science methodology to a facilitation paradigm (problem structuring methods being an exception, as they were specifically developed within a facilitation paradigm in mind). We believe that the facilitation paradigm places constraints in the way that a management science methodology can be designed and deployed in practice (for example, on the type of data that it requires and how it displays information). There is some exciting work already taking place in this direction, for example, in the field of discrete event simulation [112–114]. Further research is required to explore novel ways for redesigning other management science methodologies as facilitated modeling approaches.

Concluding, we believe that the management science community has much to gain in better understanding and further adopting the facilitated modeling approach. The nature of modern organizations, less hierarchical, more networked, with increasing distributed knowledge and power, tends to favor

this type of intervention, particularly for problems characterized by high levels of complexity, uncertainty, and conflict. We hope this article stimulates further research into facilitated modeling, and encourages more management scientists to adopt this mode of organizational intervention.

Acknowledgments

Part of this article is based on research work published by Franco and Montibeller in 2010 [7]. We would like to thank Larry Phillips for encouraging the development of this article.

OPERATION RESEARCH IN GOLF

WILLIAM J. HURLEY
Department of Business
Administration, Royal Military
College of Canada, Kingston,
Ontario, Canada

INTRODUCTION

According to the National Golf Foundation [1], the golf industry generated \$76 billion in direct expenditures on goods and services in the United States in 2005. This same report estimates the economic impact to be in excess of \$195 billion. Golf facility revenue (green fees, memberships, etc.) alone generated some \$28 billion in revenue. By comparison, the revenue generated from all spectator sports, including baseball, basketball, football, and hockey was \$24.4 billion. All this is to say that golf is big business. And given its growth in popularity over the last several decades, it is likely to continue. Given these expenditures and the interest, it is appropriate to ask whether there is a role for operations research (OR). Consequently, I describe how OR has been applied and opportunities for its further use.

HOGAN

Without a doubt, golf's first OR scientist was the American virtuoso, Ben Hogan. Hogan is on just about everybody's top-five all-time list, a list that would include Tiger Woods, Jack Nicklaus, and Bobby Jones. But Hogan was different. Whereas Woods, Nicklaus, and Jones were child prodigies, with blue-chip amateur records accumulated in their teens (Jones was an amateur his whole career), Hogan had little success as an amateur and only started to win consistently on the PGA Tour when he reached the age of 30. In fact, Hogan had to leave the Tour three times because he ran out of money. Yet, in time, he became one of the best players of all time.

One of the measures of his greatness is what other great players thought of him. When Jack Nicklaus was asked about his dream foursome, he responded that it would be Bobby Jones, Walter Hagen, and Hogan—Jones and Hagen because he had never played with them and Hogan because “I’d want him as my partner.” Tiger Woods’s foursome is Jones, Nicklaus, and Hogan. When Nicklaus was asked whether Woods was the best ball-striker he had seen, he responded “No, no—Ben Hogan easily.” (*Golf Digest*, 2004).

In my opinion, Hogan’s triumph was the result of a keen scientific intellect (even though his formal education in science was limited to whatever he got in high school) and an almost autistic preoccupation with trying to discover how to hit a golf ball properly. His practice sessions were legendary—4 hours in the morning and 4 hours in the afternoon hitting approximately three balls per minute. He discusses the role of practice in his famous instructional book, “Five Lessons: the Modern Fundamentals of Golf” [2]:

How then do you build a swing that you can depend on to repeat in all kinds of wind and weather, under all kinds of presses and pressure? Having devoted the bulk of my waking hours (and a few of my sleeping hours) for a quarter of a century to the pursuit of the answer, I now believe that what I have learned can be of tremendous assistance to all golfers. That is my reason for undertaking this series of lessons. I do not propose to deal in theory. What I have learned I have learned by laborious trial and error, watching a good player do something that looked right to me, stumbling across something that felt right to me, experimenting with that something to see if it helped or it hindered, adopting it if it helped, refining it sometimes, discarding it if it didn’t help, sometimes discarding it later if it proved undependable in competition, experimenting continually with new ideas and old ideas and all manner of variations until I arrived at a set of fundamentals that appeared to me to be right because they accomplished a very definite purpose, a set of fundamentals which proved to me they were

right because they stood up and produced under all kinds of pressure. To put it briefly, the information I will be presenting is a sifting of the knowledge I've tried to acquire since I first met up with golf at the age of 12 and knew, almost immediately, I wanted to make the game my lifework.

If Hogan's approach is not traditional OR, I am not sure what is. There was a continual experimentation with his swing until he was satisfied he had found a set of fundamentals that would stand the test of the PGA Tour.

There is no question that Hogan discovered a number of principles that modern golfers employ. Here is an example. I invite the reader to look at the following YouTube video clips of the golf swings of Bobby Jones and Tiger Woods, two swings from quite different eras:

Jones: <http://www.youtube.com/watch?v=d5XeIFcLyGw&feature=related>

Woods: <http://www.youtube.com/watch?v=cHcP6X7dEUo>

It is clear from Hogan's book and some of the stories of him instructing younger players that he felt that the lower body had to be as "quiet" as possible on the backswing, that part of the swing where you take the club back to the point where you are going to begin your downswing. So first look at Woods's swing. You will note that his right knee is absolutely fixed over his complete backswing. It only changes its position through the downswing as he shifts his weight from his right side to his left. His lower body just does not move much over the backswing. Now look at Jones's swing. Note that his lower body is much more active than Woods'. The two swings are like day and night.

I would ask the reader to do a further experiment. Try swinging a golf club keeping your lower body fixed and rotating only from the waist up. On the backswing, you will note that the muscles of your lower back and upper legs—the engine of the golf swing—really feel like they are coiling and ready to spring once the downswing begins. In my opinion, this quiet lower body does two things. It helps you to hit the ball straighter and generates more power to hit it further. This, then, is one

of the swing principles that Hogan brought to the game as a result of his experimentation.

In a 1955 *Life Magazine* article, published after his competitive career was essentially finished, Hogan supposedly revealed his "secret," the change he had made in his swing that allowed him to win more consistently. In that article, Hogan described these changes to be a weaker grip (his left hand rotated slightly to the left) and the position of his wrists at the top of his backswing (his wrists were pronated). With these adjustments, he argued, he was able to hit his signature power fade (a shot that moves slightly left to right for a right-handed golfer). But there remains some doubt that this was his real secret. In fact, those who knew him well suggested that his wisdom "I found it in the dirt," was closer to the truth. Of course, he was suggesting that a golfer needed to go to the practice tee and stay there until he or she found a swing that worked. In other words, Hogan felt that what we would call an OR approach—experimentation to see what works and what does not—was at the heart of playing better golf.

OPERATIONS RESEARCH AND THE PROBLEM OF GETTING BETTER

There has been significant research published on the nature of the golf swing and how to improve one's game. The vast majority of this has been in the field of biomechanics. The interested reader is referred to the collections in Refs 3–6. These volumes are essentially the proceedings of the four World Scientific Congress of Golf conferences. Representative titles include "Back Pain in Novice Golfers, A One-year Follow-up," "The Biomechanics of the Shoe-ground Interaction," and "Spine and Hip Motion Analysis During the Golf Swing." However, there are a few articles that are pure OR and I consider some of these in each of the following sections.

Putting

The renowned shortgame instructor, Dave Pelz [7], presents some convincing evidence that most golfers do not play enough break in their putts. They consistently hit putts

that end up below the hole on both left- and right-breaking putts. Pelz posits that this is a result of a poor read of the line and his advice is to assess the break of the putt from a position behind the ball and along the aim line (the direction in which the putt has to be hit in for it to just fall into the hole).

When assessing how hard to hit a putt, there is an old aphorism “Never up, never in.” This means that the putt has to be hit with enough speed so that it passes the hole if it misses, otherwise it has no chance of going in. But if you hit it too far past the hole, the next putt is more difficult and a three-putt is a possibility. Pelz suggests that, when a golfer is trying to maximize the probability of a one-putt, all putts should be hit so that they stop no more than 2 ft past the hole. Hoadley [8] develops a slightly different rule. On the basis of a Markov chain analysis for putting on a flat green, he suggests the heuristic rule that the distance past the hole should be 2 ft times the probability of making the putt. This advice makes sense. For very short putts, the rule really does not matter; for longer putts, it suggests that you try to get the ball just slightly past the hole. For instance, if you have a 30-ft putt, it is unlikely that you will make it. Hence, the aim should be to get it just by the hole and do no worse than a two-putt. As my colleague Mark Broadie has pointed out, one of the difficulties with his analysis is that his parameters are suspect. For instance, for PGA Tour professionals, he assumes that one standard deviation of distance error from 60 ft is about 13 ft. This is quite high. Nonetheless, the form of his rule makes sense.

The most sophisticated treatment of putting I have seen is the model developed by Bansal and Broadie [9]. Their model is based on a characterization of putter ability and a physics model based on putt trajectory and holeout considerations. The optimal strategy is the solution of a difficult dynamic stochastic programming problem. They use simulation to solve for optimal strategies for specific parameter sets. The resulting strategies are roughly equivalent in form to those produced by Hoadley.

The Long Game

If you have time to practise, how should you allocate it? The aphorism “Drive for show, putt for dough” would suggest that the majority should be spent on your short game (putting, chipping, and sand play) rather than the long game (woods and irons). What does the evidence suggest?

Berry [10] looked at PGA Tour performance statistics. He regressed a PGA Tour professional’s score on a number of factors, including driving ability (both length and accuracy), putting ability, sand save percentage, chipping ability, and iron play. He found that the factor that made the largest contribution to lowering scores was putting ability, followed closely by driving ability. Consequently, he rephrased the dictum to “You drive for dough and putt for more dough.” While this evidence is suggestive, we would need to understand the relative productivities of an hour spent on the driving range and the practice green before we could say for sure. Moreover, the data his analysis is based on are for Tour professionals, not the average amateur golfer.

There has been an interesting line of research beginning with Cochran and Stobbs [11] and continued by Landsberger [12], which attempts to assign a value to each shot in a round of golf. The most recent work is by Broadie [13]. He first defines the idea of *fractional par*, the average number of strokes that a scratch golfer needs to complete a hole. By way of example, a 140-yard par 3 hole might have a fractional par of 3.2. Suppose that you have 200 yards left into a par 4 hole. Then the fractional par might be 3.6. He defines *shot value*, v , to be the fractional par value before the shot, f_s , less the fractional value after the shot, f_e , less 1, or

$$v = f_s - f_e - 1. \quad (1)$$

As Broadie points out, this formula must be adjusted for penalty strokes. For instance suppose on a par 4 with a fractional par of 4.4, you hit your drive out of bounds. Then under the rules of golf you must hit another ball off the tee and incur a penalty so the

value of the first shot is

$$v = 4.4 - 4.4 - 2 = -2. \quad (2)$$

Here is another example. Suppose that the fractional par before you hit your second shot into a par 4 hole is 3.6 and you hit the ball to 10 feet and at that point your fractional par is 1.7. Then the value of the shot into the green is

$$v = 3.6 - 1.7 - 1 = 0.9. \quad (3)$$

We interpret this as 0.9 strokes better than what the average scratch golfer would do with the same shot.

Broadie argues that this shot value measure could be used in a variety of ways. One could use it to measure a golfer's *consistency* in the following way. We could classify shots into three types: *awful* shots, *typical* shots, and *great* shots. Awful shots have a value less than -0.8 ; typical shots are between -0.8 and $+0.8$; and great shots have a value exceeding 0.8 . A golfer could classify each shot over a number of rounds and in the process develop a picture of where he or she was falling down. For instance, it might be that the majority of awful shots are the result of poor putting. This would indicate that the golfer should devote relatively more practice time to putting.

I think Broadie's approach has considerable merit. He has developed a software program, *Golfmetrics*, which enables a golfer to record shots on six golf courses. Over time, a golfer could input individual shots from each round and from these data determine what he/she ought to practise to improve. By way of example, he analyzed shots from a group of players who normally shot between 84 and 97. His complete data set for this group and four others included 40,000 shots over 500 rounds of golf from over 130 golfers. Sample average shot values for four types of shots are shown in the following table:

<i>Putting</i>	-2.3
<i>Long game</i>	-9.3
<i>Short game</i>	-3.4
<i>Sand game</i>	-0.6
Total	-15.6

In total, these golfers are some 15.6 shots worse than a scratch golfer. Where they loose the most is in the long game (-9.3) and short game (-3.4). This would suggest that such golfers should be spending relatively more practice time on their long games but, again, it really depends on the marginal productivities of long game practice relative to those in the other areas.

OPERATIONS RESEARCH AND THE HANDICAP PROBLEM

One of the fundamental problems in golf competition, whether a friendly Nassau or an amateur tournament, is the setting of handicaps for individual golfers so that a competition is fair. For instance, if one golfer regularly shoots 75 and another shoots 85, how many strokes should the better player give to the other so that the competition is fair? This problem has received a lot of attention over the last 40 years. The interested reader is referred to papers by Bingham and Swartz [14], Pollock [15,16], Scheid [17-19], and Swartz [20].

In golf, there are two basic kinds of competitions: *match play* and *medal play*. Match play is a competition between two players where a particular hole is either tied, won, or lost. The golfer winning the most holes over 18 is then the winner of the match. With medal play, the winner of the competition is the competitor taking the fewest strokes. Most amateur tournaments tend to be medal play. To make these tournaments fair, a golfer's course-specific handicap is subtracted from his gross score to arrive at a net score and typically prizes are given on the basis of both net and gross scores.

The handicap systems in the United States

and Canada are essentially the same except for some minor differences in equitable stroke control—the term given to the maximum a golfer can count on any given hole for the purposes of computing a handicap. The systems of the Royal and Ancient and Australia are fundamentally different than those used in North America.

Under current North American handicapping systems, Bingham and Swartz [14] have shown that stronger golfers have the advantage in match play. Yet in handicapped tournaments with many players, weaker players have the advantage. So the question is how you alter the current systems to make them more equitable.

As Swartz [20] argues, golf scores are, by their nature, random and fluctuate around a golfer's true ability. Consequently, the problem of constructing equitable handicaps is, at its heart, a statistical problem. Here is roughly the way the system works in Canada. For each round, a differential is calculated according to

$$D = 113 \left(\frac{X - R}{S} \right), \quad (4)$$

where X is the golfer's score (adjusted for equitable stroke control), R is the course rating, and S is the course slope rating. Typically the rating, R , is what a scratch golfer would score on the course and S is an additional factor that helps measure course difficulty. Next a factor, F , is calculated by looking at the best 10 values of the golfer's last 20 differentials. Let the last 20 differentials be $D_1, D_2, \dots, D_{20}$ and let the 10 best (smallest) be represented by

$$D_{(1)}, D_{(2)}, \dots, D_{(10)}. \quad (5)$$

Then the factor is given by

$$F = 0.096 (D_{(1)} + D_{(2)} + \dots + D_{(10)}). \quad (6)$$

To get the course handicap, we calculate

$$FS/113 \quad (7)$$

and round it to the nearest integer.

This system has some obvious flaws from a statistical perspective. For instance, why

calculate the handicap on only the best 10 differentials? On statistical grounds, such a calculation ignores information and is not likely to be as efficient as one that uses more differentials. Swartz has suggested the following change. Rather than the factor, F , he calculates what he terms a mean, $\hat{\mu}$, given by

$$\hat{\mu} = \sum_{i=1}^{16} w_i D_{(i)}, \quad (8)$$

where $w_1, w_2, \dots, w_{16}$ are appropriately chosen weights.

To get at a good set of weights, suppose that a golfer's gross scores are normally distributed as suggested by Scheid [18] and Bingham and Swartz (1990). If this is the case, then

$$113 \left(\frac{Y - R}{S} \right) \sim \text{Normal}(\mu, \sigma^2), \quad (9)$$

where Y is the gross score, and μ and σ^2 are parameters that characterize a golfer's skill level and consistency, respectively. If the weights, $w_1, w_2, \dots, w_{16}$, are chosen properly, then not only is $\hat{\mu}$ unbiased ($E(\hat{\mu}) = \mu$), but it is also BLUE (best linear unbiased estimator), which is a very interesting result. These are nice properties and Swartz goes on to show that his new system substituting $\hat{\mu}$ for F results in a fairer system.

One of Swartz's difficulties in the design of a new system is that he is working with the Royal Canadian Golf Association and it is their wish that the new system not be too different than the old. Given the normal ups and downs in individual golf games over time, let us suppose that a handicap based on 20 scores is reasonable. Why then does he choose the best 16 rather than all 20 or some other form of truncation, say removing the three best and three worst scores? In a personal communication to me, Swartz explained that amateur golf scores are actually slightly skewed to the right. This is interesting by itself because it is certainly consistent with sandbagging (the claim that some golfers either do not register some of their good scores or inflate some of their actual scores). In this regard, it is interesting

to note that Grober [21] finds that PGA Tour scores are not skewed to the right. Swartz goes on to explain that “the censored data has better fit as a censored normal than the full sample has as a normal. I found that 16 gave roughly the best fit.”¹

As Swartz and others have pointed out, one of the difficulties with the handicapping system is that handicaps are designed to make medal play tournaments fair on the basis of net scores. So how do they work for match play? Swartz shows that his new system works fairly well for match play as well. But there are many other kinds of competitions where handicaps are used to make the game fair. One popular game at most courses is a friendly net bestball match within a regular foursome. At the course I play at, we normally match the best player with the worst in one team. With the exception of the best player, the other three players are given a number of strokes equal to 80% of the difference between their handicaps and the best player’s handicap. This arrangement has evolved over time and, in my judgment, works quite well. It would be interesting to see why it works so well.

OPERATIONS RESEARCH AND GOLF COURSE OPERATION

A number of researchers have looked at the problems associated with golf course operations. Shmanske [22] has written an interesting book that takes an economic approach to some of these problems. Representative OR work would include Refs [23–25]. These papers employ a process simulation to study the relationship among: the interval between tee-off times at the first hole; the duration of a round; and the throughput of a given course over a typical day.

The simulation model developed in Ref. 23 offers some interesting results. For the course they study, they show that there is only a slight decrease in the number of rounds played over a day if the tee time interval

at the first hole is raised from 6 to 10 min. But this increase in the tee time interval decreases the length of the average round by over an hour. This is a substantial decrease and would surely increase the quality of a round. This result also demonstrates that the tee time interval at the first hole is an important consideration for golf course managers.

In addition, Tiger *et al.* [23] look at where the bottlenecks are on the golf course they studied. The biggest bottlenecks occurred on two par 3 holes. They do not give the characteristics of these holes but I suspect they are difficult. At my course, we have two difficult par 3s and one is considered one of the toughest holes in Ontario. Invariably, we have to wait at both these holes. It seems to me that golf course designers need to look very carefully at where difficult par 3s are placed on a course and what the rules are for playing them. At some courses, players reaching the green on a difficult par 3 are asked to waive the players behind to hit their tee shots before the players on the green putt out. In my view, this is a good rule as long as the players at the green can move to a safe place. These simulation models can also be used to look at other rules such as compulsory cart rules to determine their effect on speed of play and throughput.

OPERATIONS RESEARCH AND STRATEGY FOR GOLF TEAM COMPETITIONS

Operations researchers have always had a keen interest in team strategies in sports competitions. Golf is no exception. Mulvey *et al.* [26] focus on College team selection in the United States. I have looked at some of the decisions that a Ryder Cup captain has to make [27–29]. There are some who suggest that a captain’s decisions are not that important. For instance, Jaime Diaz [30] argued that being Ryder Cup captain was “the most over-rated job in sports.” And some of the captains have felt this way as well. Jack Nicklaus, arguably the greatest player ever and Ryder Cup captain twice, said this [30]: “I don’t think the captain’s role really affects the result very much.” On another

¹Personal communication by e-mail dated March 19, 2009.

occasion he remarked that his job required making a few speeches and making sure his players had fresh towels, sunscreen, and tees [31]. Regardless of their importance, some of these decisions are quite interesting OR problems. So in this section I sketch a few of these and describe how OR can help.

The Ryder Cup is a very prestigious golf competition played between two teams representing the United States and Europe. Since it is such a great honor for a golfer to be selected to one of these teams, both teams comprise the best European and American golfers. The competition is held once every two years at sites that alternate between the United States and Europe. It is a three-day competition. On the first two days, the teams play eight “foursomes” and eight “four-ball” matches. These are two-man team match-play competitions. In four-ball matches (equivalently bestball matches), each player from a team plays his own ball and the score for a team on a hole is the lowest of their two scores. In foursomes matches the players from a team alternate shots. On the final day of competition, 12 singles matches are played. Each team captain submits an ordered list of golfers (a *slate*), and the matches are determined from these slates: USA1 versus Europe1, USA2 versus Europe2, and so on.

In my view, some of the interesting decisions are as follows:

1. *Which Golfers Should Be in the Team?* For the 2008 Ryder Cup, US captain Paul Azinger had four captain’s picks rather than the two that previous captains had. While he did not say too much about how these selections were made, it is clear that several were made just before the formal announcement.
2. *How Should a Captain Select the Slate for the Final Day of Competition?* In recent years, much has been made of front-end loading—putting the best players in the team out early in the Sunday singles matches. The question is whether this is the right thing to do.
3. *How Should a Captain Select Four-Ball and Foursomes Teams?* In the 2004 matches, US captain Hal Sutton paired

Tiger Woods and Phil Mickelson, arguably his two best players. Even if these two liked one another, the question is whether it was the right thing to do.

So how can we use OR to help answer these questions?

Ryder Cup Team Selection

Up to the 2008 Ryder Cup, US team selections were based on points accumulated for the two years prior to the competition. The top 10 players on this list were automatically in the team. The remaining two players—the wild cards—were selected by the captain. For the most recent Ryder Cup, US team captain Paul Azinger convinced the PGA that the automatic selections should be based on only 2008 PGA Tour results and that only eight of these selections would be automatic. This gave Azinger four wild-card selections. The strategy was clearly to select as many players as possible who were playing well at the time of the Ryder Cup. Azinger never discussed the precise details of how the wild-card selections were made. However, it is clear that the decision was not made until just before they had to be made.

There has been some interesting statistical research on characterizing the performance of PGA Tour players. This would include the work of Berry [32], Puterman and Wittman [33], McHale and Forrest [34], and Connolly and Rendleman [35]. I think the Connolly and Rendleman approach would be quite useful in the identification of Ryder Cup wild cards. They propose a method that breaks down an individual golfer’s scores into skill-based and unexpected components as a function of time using the smoothing spline model of Wang [36]. They find evidence of significant positive first-order autocorrelation in their error structure for 10% of the golfers in their sample. Hence, they provide statistical proof that there is method in Azinger’s madness of trying to get the players that are “hot” at the time the Ryder Cup is played. This result is also confirmed by the work of McHale and Forrest [34]. Moreover, Connolly and Rendleman’s estimates of the time-varying

skill for the players under consideration might be very useful to future Ryder Cup captains.

Choosing the Order of Play for the Singles Matches

Consider a simple variation of the actual problem. Two teams, the United States and Europe, have only two players: a very good golfer (V) and a good golfer (G). The probabilities for the US players winning individual matches are specified in the following table:

		Europe	
		Very Good (V)	Good (G)
US	Very Good (V)	$1/2$	p
	Good (G)	$1 - p$	$1/2$

We choose p to be a number bigger than $1/2$ since a very good golfer is assumed to have a better than even chance to beat a good golfer. Note that these probabilities are symmetric in the following sense. The US V golfer has a 50–50 chance against his European counterpart and a probability $p > 0.5$ of beating the European G golfer. This same property holds for the European V Golfer. By extension, both G golfers have a similar symmetric property.

Suppose that the Americans have not had a very good weekend so far, and to win the Ryder Cup, they must win both matches. We assume that no match can end in a tie. How should each captain choose his slate?

Each captain has two pure strategies: (V, G) and (G, V) The payoff matrix is shown below:

		Europe	
		(V,G)	(G,V)
US	(V,G)	$1/4$	$p(1 - p)$
	(G,V)	$p(1 - p)$	$1/4$

Each element of the table is the probability that the United States wins the Ryder Cup for the particular pair of pure strategies.

This type of game is known as a *coordination game*. Since $p(1 - p)$ is always less than $1/4$ for $p > 0.5$, the United States would like to pick (V,G) if Europe picks (V,G) and (G,V) if Europe picks (G,V). It is in the United State's best interest to have competitive matches; it is in Europe's best interest to have mismatches. Therefore, a side will have an advantage if it can somehow discover what strategy the other will use. Game theory suggests that it is in each side's best interest to keep its choice of slate secret.

Given this payoff matrix, the optimal mixed strategy for each side is to use a coin to pick a slate. That is, each captain would choose (V,G) with probability $1/2$ and (G,V) with probability $1/2$. Equivalently each could draw names out of a hat. In Hurley [29] I show that this strategy is optimal under more general conditions.² The critical assumption giving this result is that golfers' individual probabilities of winning a match are unaffected by the order of the matches. This assumption is discussed more fully in Ref. 28.

Constructing Bestball Teams

In Ref. 27, I look at the problem of how to construct four bestball teams from eight golfers of heterogeneous ability assuming the other side has the same eight golfers. I distinguish two strategies. The *Unbalanced* strategy puts together the pairings (1,2), (3,4), (5,6), and (7,8) where 1 is the best of the eight golfers and 8 is the worst; the *Balanced* strategy forms (1,8), (2,7), (3,6), and (4,5). The article suggests that the *Balanced* strategy is the best. But what is surprising is that the advantage is relatively small. So if a Ryder Cup captain felt that some of his *Balanced* pairings did not offer good "chemistry", and therefore moved away from the *Balanced* strategy, the cost to his side would be small at best.

²My colleague Hamdy Taha has pointed out an error with the proof of the general proposition given in the appendix of Ref. 29. It has been repaired and the revised proof is available from the author by request.

SOME INTERESTING PROBABILITIES

There are a number of interesting probability calculations that we could make:

1. *The Probability of the Hogan Grail.* James Dodson [37], in his biography of Hogan, tells this story. Jimmy Demaret, a fellow professional, was leaving the club house at Oak Hill after a tournament round in the mid-fifties and saw Hogan on the range, illuminated by car head-lights, hitting shots into the night. Demaret approached Hogan and remarked that he did not understand why he was practising when he had shot 64 that day with 10 birdies. Hogan responded: "Jimmy, if a man can make ten birdies in a round, there's no reason in this world why he can't birdie every hole." What is the chance, then, that a PGA Tour golfer could have a round with 18 birdies?
2. *The Probability of Shooting 59.* The Hogan Grail aside, there have been some remarkable rounds of golf. One standard is a round of 59. At the professional level, this was first accomplished by Al Geiberger on June 10, 1977, at the Danny Thomas Memphis Classic at the Colonial Country Club. Chip Beck and David Duval have also shot 59. What is the chance that a PGA Tour player would shoot 59?
3. *The Probability of Some of Tiger Woods's Winning Margins.* In 2000, Tiger Woods had a remarkable summer by any measure. He was the first golfer since Hogan in 1953 to hold three of the four major championships. He won the US Open by a remarkable 15 shots and then the British Open by 8 shots. In the modern era, these winning margins are not even close to the normal margin of 1 or 2 shots. Consequently, it would be interesting to examine what these margins tell us about Woods' abilities.
4. *The Probability That Byron Nelson's Mark of 11 Successive PGA Tour Wins Will Be broken.* In 1945, Byron Nelson won 11 consecutive PGA Tour

events. This is a remarkable feat by today's standards. The interested reader is referred to Grober [21] for the calculation.

5. *The Probability of the Miracle at Brookline.* After the first two days of the 1999 Ryder Cup matches, the US team was down 10 points to 6 to the European side. The United States won 8 1/2 of a possible 12 points over the Sunday singles matches to claim the Cup. This was the largest come-from-behind victory in Ryder Cup history. What, then, is the chance that this comeback happens assuming the teams were identical?

In unpublished work, I have documented the calculation of each of these probabilities with the exception of 4. By way of example, suppose that we calculate the probability of the Hogan Grail. Let us suppose that a particular course comprises four par 3s, 10 par 4s, and four par 5s. Let us consider Tiger Woods. On the basis of 2006 PGA Tour statistics, Woods' chances of birdies on each type of hole are estimated as follows:

Type	Probability of a Birdie
Par 3	0.1490
Par 4	0.2179
Par 5	0.5796

Woods' probability of a birdie on a par 5 hole is the sum of his frequency getting either a birdie (0.5341) or an eagle (0.0455). Consequently, his probability of at least birdieing every hole is

$$(0.1490)^4(0.2179)^{10}(0.5796)^4 = 10^{-11}. \quad (10)$$

If there are roughly 20,000 PGA Tour rounds played per year, my estimate is that the Hogan Grail should occur roughly once every 3.5 million years. In the pantheon of sports records, we are much more likely to see a 57-game hitting streak in baseball.

Acknowledgments

I would like to thank Mark Broadie and Tim Swartz for their very helpful comments on an earlier draft of this article.

OPERATIONAL RESEARCH SOCIETY OF INDIA

BANI K. SINHA
Indian Institute of Management
Calcutta, Calcutta, India

HISTORY

The Operational Research Society of India (ORSI) is a national forum set up with the objective of promoting the education and applications of operational research (OR) in business, industry, and other organizations, and also to improve the quality of human lifestyle. It was established in 1957 with the late Prof. P. C. Mahalanobis, the then Deputy Chairman of Planning Commission, Government of India and founder of Indian Statistical Institute, as the founder President of the Society. The Society is one of the earliest members of the International Federation of Operational Research Societies (IFORS), having joined it in 1960, the second year of formation of IFORS. It is the first among the developing countries to become a member of IFORS. The affiliation continues. It is also an active member of the Asian Pacific Operational Research Societies (APORS).

Since inception, the Society has grown in both stature and strength. In the 1950s, the number of OR scientists in the country was limited. Chapters of the Society are being setup from time to time throughout the country with the growth of membership. The headquarters of the Society is located in Kolkata, with 11 chapters spread throughout the country. The number of members was 777 as of June 30, 2009.

NOTEWORTHY ACCOMPLISHMENTS

India lacked facilities for formal education in OR during the early 1960s. The Society introduced a course in 1973, the two-year

graduate program in OR, following the distance-learning mode. The course is recognized by the Government of India. Examinations are held in the month of May every year.

The Society holds annual conventions when practitioners and academicians in OR and allied fields from industry as well as educational institutes in the country and abroad take part, exchange knowledge and deliberate on the latest developments. The themes of the conventions are listed in the appendix. Besides, the Society organized the following international conferences:

- International Conference on Transportation in New Delhi;
- The IFORS, the sponsor of International Conference on Operational Research for Development (ICORD), has been interested in the role of OR in developing countries and for development in general. ICORD formally started in 1992. The aim of this conference has been to provide a forum for discussion on the role, relevance, and appropriate approach of OR for development and in developing countries. There are certain basic approaches to organizing the specialized conference ICORD. These, amongst others, are to ensure and encourage OR workers from developing countries to participate, allowing adequate time and environment for meaningful discussion, developing appropriate agenda and action plan for furthering the cause of ICORD, and the like;
- ICORD-I—The first ICORD was held in at the Indian Institute of Management in Ahmedabad (IIMA), India, from December 14–16, 1992. Though IFORS, ORS of Britain, and ORSI lent their names to the conference; no support in any tangible form came from them. Major financial support came from the Tata Iron & Steel Co. Ltd. The Council of Scientific and Industrial Research of

Government of India also supported the conference financially. IIMA, the venue of the conference, provided infrastructural support to the conference. The Commonwealth Secretariat, London, provided travel and other support to some of the participants toward attending the conference and also toward organizing a specialized workshop for these participants. A position paper titled "Ahmedabad Declaration" was produced on the basis of the deliberations at the conference. This formed the basis of various initiatives on the part of IFORS toward OR for development. In addition, after an editorial review process, a few selected articles from the conference were published in the form of a book titled "Operational Research for Development," edited by Jonathan Rosenhead and Arabinda Tripathy.

Approximately, 100 participants from nearly 20 countries attended the conference. The countries represented included Australia, Bangladesh, Brazil, Canada, Greece, Iran, Ireland, India, Kenya, Malaysia, Nigeria, Peru, Singapore, Sri Lanka, South Africa, United Kingdom, United States of America, and Venezuela.

- ICORD-V was also held in Jamshedpur, India, from December 19–21, 2005.
- ORSI is the founder member of the APORS under IFORS. The regional conference APORS 2003 was held in India during December 8–11, 2003. Dr. M.C. Puri from the Department of Mathematics, Indian Institute of Technology, Delhi, India was the Guest Editor for the feature issue on "OR and its Applications" from APORS 2003.
- The latest APORS conference was held in India, for the third time, from December 6–9, 2009. The theme of this conference was "Operations Research for Emerging Economies." The Interface Description Language (IDL) Lecture was delivered by Dr. Jonathan P. Caulkins on "Providing a Scientific Basis for Managing Illegal Drug Problems," and the plenary session was

delivered by Dr. Elise del Rosario, President, IFORS on "Operations Research: A Powerful and Versatile Discipline."

The other main highlight of the conference was "Teaching Effectiveness Workshop," which was conducted by (i) Dr. Tom Grossman on "Success in Teaching Operations Research to MBAs: Philosophy, Goals, Content, and Approach"; (ii) Dr. Jill Hardin on "Exploring Best Practices in OR/MS Education"; (iii) Dr. G. Raghuram on "Use of Cases for Teaching OR/OM/Modeling"; (iv) Dr. Jim Cochran on "Developing Cases for the Quantitative Classroom: Examples and Advice," and (v) Dr. Ashok K. Mittal on "Fostering Effective Operations Research Education through Active Learning."

Amongst many pioneering applications of OR in India, the major ones are as follows:

- Dr. Jagjit Singh, the second President of the ORSI was the pioneer in introducing OR in Indian railways.
- Dr. G. Raghuram, a past President of the ORSI has been a pioneer in OR applications in Indian rail transport and infrastructure management.
- Dr. G. Raghuram *et al.* developed "Strategies to Handle Pilgrim Population at Tirumala" in 1999.
- Dr. N. Ravichandran developed "A Process-Oriented Approach to Waiting Line Management in a Large Pilgrimage Center in India" in 2005.

Two of the past Presidents of ORSI, namely, the late Dr. Bani P. Banerjee and Prof. S.P. Mukherjee held the post of Vice President of IFORS. In particular, Prof. S. P. Mukherjee was the Vice President of IFORS during the period from 2004 to 2006.

PUBLICATIONS

The Society has been publishing its flagship journal, OPSEARCH, every quarter since 1964. OPSEARCH is the first journal on OR

published in a developing country. The post of Editor-in-Chief of the journal has been held by eminent OR scientists like the late Prof. N. K. Jaiswal, who was the first to receive a doctorate in OR in India from the Delhi University. Prof. Kanti Swarup, an eminent OR specialist followed the footsteps of late Prof. N. K. Jaiswal.

The journal publishes articles on applications and modern developments in OR and allied fields. Each and every article published in the journal is subjected to reviewing by experts in the respective fields. The journal is highly acclaimed by professionals and academicians in India as well as abroad. The abstract of the articles are also published in International Abstracts in Operations Research (IAOR) monitored by IFORS.

Currently, OPSEARCH is being published by Springer India Pvt. Ltd. The hard copies of the journal are distributed to the members and e-copies are available on-line for others.

MEETINGS

The Society is governed by a nationally elected Central Council. The election is held every two years. Three to four meetings of the council are held every year and the annual General Meeting of the Society is held during the annual convention in December every year.

The Society has initiated the Dr. M. C. Puri memorial "Lifetime Achievement" award to recognize a distinguished OR professional from amongst its members every year in its Annual General Body meeting. Dr. M. C. Puri, retired Professor of Mathematics, Indian Institute of Technology, Delhi, and an eminent OR professional, became a victim of terrorist attack in the Indian Institute of Science, Bangalore, on December 28, 2005 while he was attending the ORSI's annual convention there. The "Lifetime Achievement" award has been awarded to three professionals so far, as given below:

- Prof. R. N. Kaul from Delhi in 2007
- Prof. M. R. Rao from Tirupati in 2008
- Dr. Subir Chowdhury from Jaipur in 2009.

Of the three awardees, the most notable in terms of global recognition of research excellence is Dr. M. R. Rao, former Director of IIM Bangalore, current Emeritus Dean of ISB, Hyderabad, a world-class operations researcher, and a past President of ORSI.

PAST PRESIDENTS AND THEIR TERMS OF OFFICE

S. No.	Name of the President	Tenure
1.	Prof. P. C. Mahalanobis	(Expired)
2.	Dr. Jagjit Singh	
3.	Mr. A. Rahman	(Expired)
4.	Dr. V. Ranganathan	
5.	Brig. K. Pennathur	(Expired)
6.	Dr. B. P. Banerjee	1971 (Expired)
7.	Dr. Subir Chowdhury	1972
8.	Col. H. S. Subba Rao	1973
9.	Prof. N. K. Barat	1974
10.	Dr. M. Krishnamoorthy	1975
11.	Prof. S. K. Srinivasan	1976 (Expired)
12.	Dr. Rangalal Bandyopadhyay	1977–1978
13.	Mr. S. M. Sundara Raju	1979
14.	Prof. S. Subba Rao	1980
15.	Dr. Utpal K. Banerjee	1981
16.	Dr. Sushil K. Basu	1982
17.	Prof. A. H. Kalro	1983
18.	Prof. P. R. Ramakrishnan	1984
19.	Prof. K. C. Sahu	1985
20.	Prof. Kanti Swarup	1986
21.	Prof. Nitin R. Patel	1987
22.	Prof. Susy Philipose	1988 (Expired)
23.	Prof. A. Tripathy	1989
24.	Dr. S. R. K. Prasad	1990
25.	Dr. Amitava Mustafi	1991
26.	Prof. K. G. Ramamurty	1992
27.	Mr. M. N. Poddar	1993
28.	Prof. B. R. K. Kashyap	1994
29.	Prof. A. K. Rao	1995
30.	Prof. S. Krishnamoorthy	1996
31.	Dr. Gopal P. Sinha	1997
32.	Dr. I. C. Sharma	1998
33.	Prof. G. Raghuram	1999–2000
34.	Prof. S. P. Mukherjee	2001–2002

S. No.	Name of the President	Tenure
35.	Prof. M. R. Rao	2003–2004
36.	Prof. P. K. Kapur	2005–2006
37.	Prof. Ashok K. Mittal	2007–2008
38.	Prof. Bani K. Sinha	2009

Recently, ORSI has started to honor its past presidents for their outstanding contribution to the society by awarding the title of “Fellow” provided the number of such Fellows is not more than 25 at any time. The current list of Fellows is as given below:

S. No.	Name of the Fellow
1.	Dr. R. Bandyopadhyay
2.	Prof. N. K. Barat
3.	Prof. Sushil K. Basu
4.	Dr. Subir Chowdhury
5.	Mr. P. C. Datta
6.	Prof. A. H. Kalro

S. No.	Name of the Fellow
7.	Dr. Jagjit Singh
8.	Prof. S. Subba Rao
9.	Prof. M. N. Gopalan
10.	Prof. P. R. Ramakrishnan
11.	Mr. V. Ranganathan
12.	Prof. K. C. Sahu
13.	Dr. S. R. K. Prasad
14.	Dr. Amitava Mustafi
15.	Prof. B. R. K. Kashyap
16.	Prof. A. K. Rao
17.	Prof. S. Krishnamoorthy
18.	Dr. Gopal P. Sinha
19.	Dr. I. C. Sharma
20.	Prof. G. Raghuram
21.	Prof. S. P. Mukherjee
22.	Prof. M. R. Rao
23.	Prof. P. K. Kapur
24.	Prof. Ashok K. Mittal

OPERATIONAL RESEARCH SOCIETY OF NEPAL (ORSN): AN INTRODUCTION

SUNITY SHRESTHA HADA
ORSN, Kathmandu, Nepal

HISTORY OF ORSN

Background

The twenty-first century is the period of challenge for global development in multidimensional sectors, ranging from the manufacturing sector, service sector, government sector, nongovernment sector, economic and social sector, gender mainstreaming, natural resources, climatic changes, environmental factors, nuclear technology, and information technology. All these sectors and few other sectors need to make decisions at various levels, such as at operational level, middle level, higher level, or sometimes global level. The interaction of two or more sectors mentioned above make the scenario more complicated, and the decision making process need more rational and some theoretical ground and advanced scientific techniques and tools.

The traditional approach or the heuristic approach used to arrive at a decision or application of some simple or advanced tools come into the category of mathematics, statistics, or management science or the operations research (OR). There are no areas in the world at present, which can be imagined without the application of mathematics, statistics, or OR subject areas.

There are various organizations in the name of Society, Association, or others on the subject areas of mathematics, statistics, management science, and the OR around the world, country-wise, region-wise, and global-wise, which work for the benefit of the personnel working in these areas, giving a platform to interact and network with each other to

share their respective knowledge and their research findings so that everybody can be aware of what is going on around the world in their areas of interest.

In Nepal also, the personnel from statistics area and working in Faculty of Management as academicians, Prof. Dr. (Ms) Sunity Shrestha Hada and Mr. Govinda Tamang of Central Department of Management, Tribhuvan University (TU) realized the need of a society of people working in this area in various sectors of Nepal and came up with the idea of bringing all of them together in one platform. Both having being exposed of the existence of Operational Research Societies in India and other countries and the regional basis, they wanted to network with these societies, and as a result, they applied for the membership in Operations Research Society of India (ORSI) in 2005 and received the life membership.

It was easy to convince colleagues of mathematics, statistics, and engineering areas, as all of them were at the same boat, as they all observed that these areas are not getting the due acknowledgement they deserve in various sectors based on their application. One simple example of the importance not given to the area OR is observed that in the Central Department of Statistics, TU, the course on OR was absent because of the scarcity of faculties in this area, where this area of OR and/or operations management is a compulsory course in management faculty, engineering institutes, and mathematics departments.

Hence, a series of meetings with like-minded colleagues, Sunity and Govinda, was successful in making a team of nine persons, as patron or the founder members and with lots of effort and preparation, got the "Operational Research Society of Nepal (ORSN)" registered duly in the office of Nepal Government at February 1, 2007. Now, the ORSN has about 50 members consisting of both life members and ordinary members in it, with a common purpose of extracting the importance of OR in the society.

Among various objectives, some of them are to advocate the OR areas in academic fields, because without the people educated with OR knowledge, scientific decision making is beyond imagination in this century. It also aims in bringing the academicians, professionals, and practitioners of OR in a single platform of ORSN and share their problems, experience, and knowledge and have in win-win situation and get benefited.

The ORSN also realizes the importance of not only the applications of OR techniques and tools in different sectors but also the theoretical development in this area and desires to encourage the theoretical foundations in Nepal as well. ORSN became 53rd national member society of IFORS and is the member of APORS from 29th November 2011.

Mission

The mission of ORSN is to be a leader organization for the OR theoretical developments and OR applications in Nepal.

Vision

The vision of ORSN is to be an organization that works for the developments of OR by the following ways:

- establishing an “Institute of Operations Research in Nepal” with responsibility of providing academic and vocational degrees of OR and its related fields;
- networking with national and international organizations working in similar fields;
- publishing an international journal of OR.

Objectives

The ORSN has the following objectives as per its constitution at the time of registration:

- to make advocacy and provide orientation in different sectors of Nepal;
- to collect and publish the materials relating to operational research for making the operational research systematic and effective;
- to organize and operate the study and research, training, discussion, seminar, and workshop in national and international levels for promoting competency of persons involved in the area of operational research;
- to provide consultancy services of operational research to institutions working in the concerned area of different sectors such as education, management, industry, business, and others;
- to make significant contribution in the development of operational research in Nepal by maintaining coordination and network with different and international institutions;
- this organization shall be a nonprofit, public-welfare, and social-welfare institution.

STRUCTURE OF ORSN

The structure of ORSN constitutes an executive committee of nine members. The ad hoc committee that worked for initial processes and the registration of the ORSN, and the journal IJORN is the founder member and the patron of the OR Society. All the founder members are life members as referred in the constitution.

Membership Eligibility

The member of ORSN must hold a master's degree in any discipline from recognized university and involve in study-teaching, research, and consultancy in areas of OR. There is no discrimination to obtain the membership from the organization on the basis of race, caste, religion, sex, and political views.

Membership Types

The type of membership is classified as follows in ORSN:

- *Founder/Patron Member.* The office bearers signing the constitution during the registration process of ORSN are the founder members, or the patrons.

All the founder members are life members. There are nine founder members of ORSN.

- *Life Member.* The executive committee grants membership to the eligible persons according to the above criteria and paying NRs. 10,000 (ten thousand rupees in Nepali currency) to ORSN.
- *Ordinary Membership.* The eligible persons can get ordinary membership by paying an entrance fee of NRs. 500 (five hundred) and can be renewed annually with a fee of NRs. 500. The fiscal year for the membership starts from first date of Shrawan and ends at last date of Asadh (mid-july) each year.
- *Honorary Member.* The ORSN can provide this membership to honor personalities who made special contribution to the organization.
- *Institutional Membership.* Institutional membership is provided to any institution who is working in OR or its related areas. The ordinary membership can be provided with an annual fee of NRs. 10,000. Also, life membership to the institution can be provided with a payment of NRs. 100,000 at a time.

The Executive Committee

The structure of executive committee of ORSN constitutes of President, Vice-President, General Secretary, Secretary, Treasurer, and four members. Later, amendment was done and 2 members are added in the executive committee, and the new executive committee includes 11 members. Only life members are eligible for being in the executive committee Table 1.

Members Election

The general meeting is regarded as an apex body of the organization. In general, the general meeting is held once in a year. In special cases, the general meeting can be held more than once in a year. The proceedings of the general meeting cannot take place unless at least 51% of the members are present in the meeting. The executive members and the officials are elected from the general meeting. The tenure of each member is of two years. A person should be life member of this organization for being a candidate of the executive committee. A person worked continuously at least four years (two tenure periods) in the executive committee of this organization can be the candidate of the president of ORSN.

Table 1. Executive Committee

Position	2007–2009 (August)	2009–2011 (August)	2011–2013 (August)
President	Prof. Dr. Sunity Shrestha	Prof. Dr. Sunity Shrestha	Prof. Dr. Sunity Shrestha

Member	—	Prof. Hirendra Man Pradhan	Mr. Vijay Lal Shrestha
Member	—	Mr. Vijay Lal Shrestha	Mr. Dipendra Purush Dhakal

The founder president shall be the honorary president of the organization ORSN. The immediate past president (IPP) will be the executive member for the consequent tenure.

The executive committee may invite any national or foreign experts or any other distinguished personalities to the meeting.

Fiscal Management

The ORSN is a nonprofit organization. There is a separate fund for the organization, and the account has to be maintained as per the format of the prevailing law of Nepal.

The sources of the fund are membership entrance and renewal fee, overhead cost received from training, research, consultancy, and other services. The ORSN also considers the grants assistance or donations, foreign grants, and assistance with prior approval from the Nepal government as the sources of fund. An annual audit must be carried out by a licensed auditor from the Nepal government within one month from the date of expiry of every fiscal year. The audited report need to be approved by the Annual General Meeting (AGM).

THE PRESIDENT OF ORSN

It has been four years since the establishment of ORSN. The tenure of the president being two years, the third president has to take care of the ORSN office. Considering the progress of ORSN and the vision and performance of the current president, Prof. Dr. Sunity Shrestha has been the president for the third tenure.

Among a number of functions, some of the duties and powers of President are to monitor and control the functions and activities of ORSN, to represent the organization, and to make the agreements on behalf of ORSN and other institutions for operations of projects, and to provide directives and policy for operations of the projects.

ACTIVITIES OF ORSN

Website

The ORSN has its own website www.orsn.org.np. It covers the members of ORSN; past,

current, and upcoming events; and the constitution of ORSN. It has a photo gallery too to support the events.

Conferences

The ORSN has successfully organized ORSN Conference 2012 on February 1 and 2, in Kathmandu with the theme "Operations Research for Sustainable Development." The IPP of IFORS, Ms. Elise Del Rosario and other distinguished resource persons and participants from India, Brazil, New Zealand, Korea, and Nepalese graced the events.

However, the ORSN always encourage its members to participate in national and international seminars and conferences throughout the world, which helps in interaction with OR experts from around the world and networking with other organizations.

Mr. Govinda Tamang, General Secretary of ORSN attended the ORSI International Conference held at Kolkata Business School, Kolkata on January 6–8, 2012 with theme "International Conference on Operations Research for Sustainable Development in Globalized Environment" and presented a paper on "Total Quality Management of Commercial Banks in Nepal."

The ORSN president Dr. Sunity Shrestha Hada attended IFORS-2011 Conference held at Melbourne on July 10–15 and presented a paper on "Relative Efficiency of Nepalese Commercial Banks."

Mr. Govinda Tamang attended the SORMS (Society of Operations Research and Management Science) seminar in NITIE Mumbai, India held on 2010 and presented paper on "Relative Efficiency of Commercial Banks"

Also, president Dr. Sunity Shrestha attended the national seminar organized by the SORMS held at Indian Institute of Technology (IIT) Madras, Chennai, India, held on December 20–22, 2009 and presented a paper on "Productivity Management in Education Sector in Nepal."

The president Dr. Sunity Shrestha and general secretary Mr. Govinda Tamang of ORSN participated in the APORS conference in 2009 (December 6–9) at Jaipuria Institute of Management (JIM), Jaipur, India. They

Table 2. Workshop

Workshop Title	Resource Persons
Introduction to lean six sigma	Dr. Charles Aubrey, Chairman, Asia Pacific Quality Organization
Food safety and quality in food service establishments: A major tourism booster	Dr. Miflora Gatchalian, Chief Executive Officer, Quality Partners Co. Ltd, Philippines
Harmonizing workplace relations for quality through labor management councils (LMCs)	Dr. Jose C. Gatchalian, Board Vice-Chairman, Development Center of Asia/Africa/Pacific (DCAAP)

presented a paper on “Effectiveness of Higher Education System in Nepal.”

Seminar/Workshop

The ORSN has organized a number of workshops individually and in association with other organizations.

Training cum workshop on “Revenue Management and Dynamic Pricing” was held at Hotel Royal Singi, Kathmandu, Nepal on January 4–5, 2009. The resource person was Prof. Goutam Dutta from Indian Institute of Management, Ahmedabad (IIMA). Thirty-six participants from 24 different organizations, including government organizations, banks, hospitals, airlines, consultancy services, universities, campuses, and electricity authorities, attended the program.

The ORSN associating with Nepal Bureau of Standard and Meteorology (NBSM) conducted postconference workshops on September 21, 2010 in Kathmandu during the 16th International Conference on Quality

(ICQ) (September 18–20, 2010) coorganized by the Network for Quality, Productivity and Competitiveness-Nepal (NQPCN). The workshop was coordinated by Prof. Sunity Shrestha, president of ORSN Table 2.

The ORSN organized one-day workshop on February 16, 2011 at Kathmandu on Knapsack problems and Project Management. The resource person was invited from University of Graz, Austria.

The ORSN also actively participated in seminar cum workshop held on March 1–4, 2011 on “Emergency Planning” organized by the Central Department of Mathematics, Nepal German Alumni Association Society (NEGAAS) and DAAD. The main resource person was Prof. Dr. Horst Hamacher, who is the IPP of German Operations Research Society.

Talk Programs

ORSN has been organizing talk programs as a regular activity (Table 3).

Table 3. Talk Programs

Date	Talk Program Topics	Resource Person
August 27, 2010	Aggregation scheme: Revisit	Prof. Dr. Devendra Chhetry, Chairman, Nepal statistical Association
September 10, 2010	Survival analysis focusing on acute liver failure	Dr. Shankar Prasad Khanal, Associate professor, Central Department of Statistics Tribhuvan University
January 20, 2011	Carbon sequestration: Local solution to global problems	Dr. Umakanta Mishra, Post Doctoral Research Scholar, University of California, Berkely
May 4, 2011	Estimating health effect coefficients attributed to ambient particulate air pollution	Dr. Srijan Lal Shrestha, Associate Professor, Central Department of Statistics, Tribhuvan University
September 5, 2011	Relative efficiency measurement: DEA approach	Prof. Dr. Sunity Shrestha Hada, Central Department of Management, Tribhuvan University, Nepal

Training

The ORSN has priority in training programs and has planned for conducting trainings on the following areas, and the training cum workshop on *Applications of Computer Technology in Statistics: SPSS 18.0* was conducted at Kathmandu on November 28–December 28, 2011.

- SPSS
- Econometrics
- Research methodology
- Optimization
- Time series

- Forecasting
- Others

Research and Consultancy

The ORSN has the future programs of conducting research in various areas of OR. It also has future plan of performing consultancies with industries in Nepal.

Journal

The ORSN has been working on publishing an international journal annually. The journal has been legally registered under the Nepal Government on 2010. The name

of the journal is International Journal of Operations research-Nepal (IJORN). Different committees have been formed to activate this. The first issue of IJORN has been published on February 1, 2012 at the occasion of the sixth anniversary of ORSN Table 4.

Institute of Operations Research

The ORSN has a highly optimistic vision of establishing an “Institute of Operations Research” in Nepal. The main purpose of the institute is to impart knowledge of theoretical development and applications of OR in various sectors.

DISCUSSION

The ORSN meets with its members about once in a month. All the members have their association with their own organizations that

ranges from universities, colleges, institutes, financial sectors, airline sectors, health sectors, government offices, and research consultancy firms. Talk program is a regular program of ORSN, where the members get opportunity to meet, interact, and discuss their academic and other activities and share their experience.

The ORSN has tie-up and collaboration relationship with other organizations in Nepal and in international institutions. It is working with “Institute of Organizations Career Development (IOCD)” in sharing the training programs and seminar/workshops. It is also working with “Nepal Evaluation Society (NES)” and “Innovative Solutions Pvt. Ltd” in research and consultancy.

The ORSN is corresponding to “University of Graz at Austria” with the initiative of Prof. Dr. Hans Kellerer for institutional interaction and exchange programs.

OPERATIONAL RESEARCH SOCIETY OF TURKEY

TANER BILGIÇ

REFİK GÜLLÜ

Department of Industrial Engineering,
Boğaziçi University, Bebek,
Istanbul, Turkey

Roots of the Operational Research Society of Turkey (ORST) go back to 1965, when the Scientific and Technological Research Council of Turkey (TÜBİTAK - responsible for the funding and coordination of government supported research) decided to establish an Operations Research (OR) unit within its organization. Halim Doğrusöz, who received his PhD in OR in the group Russel Ackoff brought together at Case Institute of Technology, established the OR unit within TÜBİTAK. He was its first chairperson until 1968.

Later, in 1975, Prof. Doğrusöz founded a graduate Operations Research and Statistics program at the Middle East Technical University, Ankara. ORST was founded March 10th of the same year by a group of fellow OR researchers including Halim Doğrusöz, Muhittin Oral, Kutay Arman, Ünver Çınar, Erkut Yücaoglu, and Ataç Sosyal. The last two names are from Boğaziçi University and Istanbul Technical University, respectively. These two universities in Istanbul had recently founded their Departments of Industrial Engineering with a strong emphasis on OR. The Operations Research and Statistics program at the Middle East Technical University later merged with the Department of Industrial Engineering in the same university. Over the years, OR education had been largely organized under Departments of Industrial Engineering in Turkey and enjoys a high reputation as a popular profession among university students. As of the end of 2009, there are 54 Industrial Engineering departments in 54

different universities with an intake of more than 4400 students every year.

One of the early mandates of ORST has been to make OR visible in Turkey. To that end, one of the first challenges of ORST had been the need to translate “OR” into Turkish. Military OR has been in existence in Turkey since 1954 within the “Scientific Investigation Council” of the Turkish Armed Forces. In 1956, the army instituted an OR unit. Although it seemed natural to use the word “Harekât” in Turkish as the translation of the term “Operations,” ORST noted the overwhelming military use of that term in Turkish and needed an alternative. They coined the term “Yöneylem” (which is an amalgamation of “direction” and “action” in Turkish) and translated “OR” as “Yöneylem Araştırması” (“Research on Directed Actions”) stripping it largely from its military meaning. When late Prof. Ackoff visited Turkey in the early 1970s, he was asked what he thought about the translation of OR into Turkish. He replied “Directed actions? So OR is actually ‘Research on Purposeful Actions.’ This is even better than the English name of the profession!” [1].

Past presidents of ORST are: Halim Doğrusöz (1975–1979), Merih Celasun (1979–1981), Ataç Soysal (1981–1989), Ömer Saatçioğlu (1989–1996), Çağlar Güven (1996–2001), Nesim Erkip (2001–2003), Haldun Süral (2003–2005), Refik Güllü (2005–2009), Taner Bilgiç (from 2009 to till date). The Society is governed by an executive committee comprising the president, secretary, treasurer, and two members. The executive committee is elected by the general assembly.

Today, ORST is a well established society with a total membership body of about 900, from both academics and industry. Major activities of ORST are the organization of a yearly Operational Research and Industrial Engineering (OR/IE) congress, and the publication of the journal *Transactions on Operational Research*. ORST is a full member of EURO (The Association of European

Operational Societies) and IFORS (International Federation of Operational Research Societies).

The first national OR/IE congress took place in Istanbul in 1975 and was organized by ORST, TÜBİTAK Marmara Research Center, and Boğaziçi University. OR/IE congress usually takes place in the summer and it is hosted by one of the universities in Turkey. In 2009, the congress was hosted by Bilkent University in Ankara. In 2010, the 30th Congress will be held in Istanbul at Sabancı University. Although the language of the congress has always been Turkish, over the years there are more sessions conducted in English and more international participation. Along with plenary speakers, tutorials, contributed and invited sessions, a student paper competition is also organized to honor the best student work of the year and prize for Excellence in Practice is awarded. Typical attendance to OR/IE congresses ranges between 250 and 350 with about 170–200 papers presented.

ORST also organizes a biannual Doctoral Colloquium for doctoral students with the aim of bringing together doctoral students from the nation to share their research and experiences. The doctoral programs in OR are relatively young but growing rapidly.

PhD degrees in OR were awarded for the first time in the late 1970s and early 1980s by the Middle East Technical University and Boğaziçi University. Owing to its popularity as a profession, Industrial Engineering departments have attracted and still attract very strong students. Many of these students have pursued graduate degrees abroad (mainly in North America) and there is a sizeable community of OR researchers and practitioners outside Turkey.

ORST began awarding a prize for *Excellence in Practice* in 2002. The objective of this award is to promote excellence in using OR while successfully solving problems of practical interest. The award also aims to coordinate the efforts of various isolated groups applying OR to practical problems.

ORST maintains a website (www.yad.org.tr) but it is mostly in Turkish. It also has access to its membership body via email lists.

OPERATIONAL RISK

RODNEY COLEMAN
Department of Mathematics,
Imperial College London,
London, UK

RISKS ARISING FROM BUSINESS ACTIVITY

You lose business opportunities while your computer systems are down. You settle a wrongful dismissal claim. You receive a penalty notice for the late filing of documents. Your employee embezzles from you. Your customer records have gone missing. A flood has breached your stock room damaging goods awaiting shipment. These are the day-to-day hazards of running a business beyond those from its money-making activities. This is operational risk, often shortened to *oprisk*. It excludes risks which result in losses from poor business decisions. Oprisk losses will generally stem from weak management, from outsourcing nonstrategic activities, or from external factors.

Operational risk events happen everywhere, not just in a business environment; for example, injuries sustained from a design weakness in playground or fairground equipment, or engineering flaws resulting in a mass recall of motor cars. Poor labeling on pharmaceutical packaging can lead to the wrong dose being administered. Swabs or instruments can be left in a patient after surgery. Attention to safety has a big role in mitigating these hazards.

Major construction projects—digging tunnels, mineral extraction, raising bridges, building skyscrapers—all need careful planning not just to support efficient operations but to minimize avoidable delays from operational risk events. Large companies involved with manufacturing, technology, telecommunications, and media services will all have operational risk management departments.

Business is entered into with the aim of generating wealth, in the pursuit of returns

on capital. In contrast, the supervision, control, and management of operational risk absorbs capital in the protection of wealth, without being directly profit generating. Indeed a major cost is often on business continuity planning, preparing for eventualities beyond the control of management that threaten the business environment. These include terrorism, civil unrest, systems failings including hacking, organized crime, and nature's worst behavior such as hurricanes, tsunamis, and volcanic ash clouds.

Measuring and modeling operational risk events is needed to answer questions of how high to build a flood barrier, how much to spend on railway safety, and how much to put into reserves to protect a bank from collapse.

Oprisk data for study are hard to come by; their publication might expose a firm's failings, and make it lose competitive advantage. The financial sector has led much of the study of operational risk, not only because losses are widely expressed in monetary terms but also since the industry is highly regulated. This is to ensure not only that our savings and pensions are safe but also that businesses and governments would be able to continue to borrow and lend following a worst case financial crisis. When the loss events are penalties imposed for contravening regulations, they enter the public domain.

Onetime categorized as the catch-all "other risks" after credit and market risk are excluded, operational risk was pretty universally considered to be unmeasurable. In 2001, however, Basel II, which set out a regulatory framework for operational risk in international banking, was to give a generally accepted definition for operational risk [1, para. 664, p. 140]. It was to be the risk of loss resulting from inadequate or failed internal processes, people, systems, or from external events. More importantly, Basel II was the driving force behind developments in operational risk management practices, the search for robust risk measurement, and the requirements of transparency through disclosure. This has made operational risk a

Figure 1. A basic risk structure.

significant topic in business and management studies. (For more on Basel II, see Box B.)

The basic operational risk structure is shown in Fig. 1. A risk management structure and an operational risk management structure follow later.

OPERATIONAL RISK EVENTS MAKE HEADLINES

Public attention gets drawn to operational risk when infrequent but high impact events occur. Fitch's OpVar database has nearly 500 events in the United States between 1978 and 2005 where the losses exceeded \$10 million. With 10 years of data, the 2004 loss data collection exercise (LDCE) has more than 100 events in the United States where the losses were \$100 million or more [2, p. 2].

Brief narratives follow on some extreme oprisk events.

- *Union Carbide.* During the night of December 3, 1984, 40 tons of poisonous gas leaked from the US owned Union Carbide pesticide factory in Bhopal, India, and settled over neighboring slums. More than half a million people were exposed to the deadly fumes. Within days, 3500 people were dead, and more than 15,000, possibly as many as 25,000, have died since. It stands as the world's worst ever industrial accident. Union Carbide

denied responsibility. The effects of the gas on survivors continues, with chronic illnesses, cancers, and children with birth defects. Environmentalists claim that the neighborhood has not been rid of toxins, said to be still polluting the local water supply.

- *Space Shuttle Challenger Disaster.* On January 28, 1986, shortly after take-off from the Kennedy Space Center in Florida, the space shuttle Challenger exploded killing all seven on board. A seal on a rocket booster motor had failed allowing hot pressurized gas to reach an external fuel tank, causing its structure to fail and the spacecraft to disintegrate.
- *Bank of Credit and Commerce International.* BCCI was closed down in 1991 after it was revealed that accumulated losses totaling more than a billion US dollars had been fraudulently hidden from auditors and regulators.
- *Sumitomo Corporation.* Between 1985 and 1999, a star copper trader at Sumitomo incurred massive losses through risky trading. It was sufficient to affect the entire copper market.
- *Barings Plc.* Barings Bank, a long established merchant bank in the city of London, became insolvent in 1995 when a young trader at its Singapore subsidiary lost £860 million from excessive and unauthorized speculation on the Tokyo stock exchange index. He hid this activity for two years. When brought to light, it was found that he had failed to hedge enormous outstanding positions, cover for which required payments that Barings could not meet. That its main assets were held offshore probably contributed to the Bank of England being prepared to let the bank fail.
- *Prudential Insurance Company of America.* The Prudential paid out \$2 billion in settlement of a class action lawsuit relating to its agents deliberately misleading purchasers throughout a period of 13 years up to 1995. More recently in the United Kingdom, there was similarly the costly endowment mis-selling scandal

of people being misled into exchanging defined company pension plans for riskier and less advantageous market-funded schemes. In December 2002 one of the insurers involved, Abbey Life, was fined a record £1 million and paid £160 million in compensation to 45,000 policy holders.

- *Hurricane Andrew.* In 1992, Hurricane Andrew swept through the south of Florida. The damage led to a \$16 billion insurance payout, a record insured loss, only exceeded with the terrorist attack that devastated the World Trade Centre in Manhattan on September 11, 2001.
- *The Global Financial Crisis of 2007–2009.* The worldwide financial breakdown began with the credit crunch, the seizing up of the markets on August 9, 2007 following problems created by subprime mortgage lending in the United States. It was the result of a bubble created by cheap borrowing, with offloaded debt insured against default. In their premium pricing, the insurers failed to take account of the risk that property values might fall with consequent defaults on mortgage repayment. The operational risk was in the lack of due diligence: the lenders in failing to check the means of their mortgage applicants, the purchasers of the debt similarly in respect of the mortgages supporting it, and the insurers in taking on the default risk. Poor business practices caused the crisis to propagate from insurers without the means to pay out on the mortgage defaults, to the banks who lent the money, and to the householders who lost their homes. This is illustrated by the fall of Northern Rock, which suffered the first run on a British retail bank in a century. (Box A.)
- *Deepwater Horizon.* On April 20, 2010, 50 miles off the Louisiana coast in the Gulf of Mexico, the Deepwater Horizon drilling rig exploded and sank killing 11 workers. Hundreds of thousands of gallons of oil began leaking daily from a ruptured pipe, causing untold environmental damage. The oil slick

washing up on the beaches threatened wildlife and businesses. The fishing industry was all but halted, and tourism was curtailed. The drilling platform was leased to the British oil giant BP from the Swiss headquartered rig operator Transocean, the world's largest offshore drilling company. The explosion happened after the US company Halliburton, the world's largest provider of services to the energy industry, laid cement casings round the well head, completing its construction. BP acknowledged that it had been unprepared for the disaster. Operational risk controls failed in this case.

- *Volcanic Ash.* On April 14, 2010, a volcano erupted through the Eyjafjallajökull glacier in Iceland and sent a cloud of ash into the upper atmosphere. For safety reasons, the airspace over parts of northern Europe was closed. With thousands of flights grounded, there was widespread disruption to travel and business activity. Travelers became stranded abroad. Airspace was cautiously reopened five days later. The previous volcanic eruption at the glacier had been in December 1821. The long passage of time since led to the 2010 eruption being called a “black swan” event, an event so unlikely as to be off everybody's radar.

RISKS AND RISK MANAGEMENT

Before considering operational risk and its management, we give a very brief introduction to risks in general and their management.

Classifying Risks

Risks are often sorted into categories, such as those given here with illustrative examples [3, p. 107].

- *People Risks.* Deliberate willful behavior such as fraud or malicious damage. Errors such as mistakes brought on by fatigue, incompetence, lack of management supervision, and inadequate staffing levels.

Box A. Northern Rock

This former Building Society (savings and loan company) had floated on the stock exchange as a bank in 1997. It moved into subprime lending in 2006, issuing mortgages in excess of 100% of property valuations, often on self-reported and unverified household incomes. It expanded quickly to become the United Kingdom's fifth largest bank, funding its rise by borrowing on money markets, securitizing its mortgage debt, and other financial instruments. When the US's \$8 trillion housing bubble burst, it became clear that Northern Rock's business model was severely defective.

The credit crunch of August 2007 caused the share price to fall fast. In September, there were depositors queueing round the block seeking to withdraw their generally modest savings. Withdrawals were also being made on-line. In December, the Bank of England stepped in by providing liquidity support, and sought a buyer, but without success. On February 22, 2008, it was taken into public ownership. Yet, it was considered to be well managed operationally.

No measures had been taken to provide for a fall in property prices. It has been reported that Lehman Brothers had underwritten £100 billion of Northern Rock's debt (collateralized debt obligations on mortgage-backed securities).

Lehman Brothers itself filed for bankruptcy on September 15, 2008. A week earlier, the giant US mortgage lenders Fannie Mae and Freddie Mac had received a government bailout, and the largest insurance company, AIG, and the largest savings and loan company, Washington Mutual, were in dire straits, lining up for support.

The response to the collapse of Northern Rock was to herald the international effort to stave off global collapse of the financial system.

- *Cumulative Interactive Risks.* Minor errors build up leading to a major loss. The effects accumulate as they propagate through a company. This is the so-called Swiss cheese model, where the holes/hazards line up, with all controls failing simultaneously. It is widely used in investigating catastrophic incidents [3, p. 113; 4, p. 234].
- *Systems and Process Risks.* Technology failure, programming errors, errors in data management, insufficient processing capacity. Lost or wrong paperwork, and inadequate segregation of duties.
- *External Factors.* The sinking of a cruise liner would severely damage the entire cruising industry, and have an immediate impact on shipping insurance premiums.
- *Randomness.* Low risk events having high impact can be due to pure chance. However unlikely, lottery jackpots are won.

We need also to understand that these categories are not necessarily mutually exclusive. Catastrophic industrial accidents at a plant can occur despite the plant having an exemplary safety record. In March 2005, there was an explosion at BP's Texas City refinery which left 16 people dead and more than 170 injured. A report on the incident found that BP had interpreted improvements in personal injury rates as indicating acceptable process safety performance. Elliott *et al.* [5] used this in the introduction to their study of the relationship between occupational illnesses and injuries (OII) and the major incidents reported to the US Environmental Protection Agency over the same period, 1996 to 2000. Their statistical analysis finds only weak evidence of a link.

A Simple Framework for Risk Management

This is given in Fig. 2.

Box B. Basel II

The Basel Committee for Banking Supervision (BCBS) was set up in 1974 as a committee of the Bank for International Settlement (BIS) to provide a regulatory framework for internationally active banks. In its Basel Accord of 1998, now known as Basel I, it settled the minimal level of capital to be held by banks as provision for credit risk and market risk. In 2001, it moved to do the same for operational risk in its New Basel Capital Accord, known as Basel II [1]. It was approved by the European Parliament in 2005, and came into effect across the entire European Union (EU) in 2008.

The accord sets out a risk sensitive way of calculating reserve capital to cover possible defaults. Institutions are required to categorize operational risk losses by event type, promoting identification of risk drivers. There is no mandated methodology.

Pillar 1 of Basel II gives three ways of calculating the operational risk capital charge, with increasing complexity, but benefiting from a reduced charge.

- The *basic indicator approach* (BIA) calculates the reserve capital simply as a proportion of gross revenue.
- The *standardized approach* (TSA) divides the activities of a bank into eight business lines (Table 2), with standard capital charges for each based on calculated risk indicators.
- The *advanced measurement approach* (AMA) requires that the banks model loss distributions of cells of a business line/loss event type grid from operational risk loss data that they themselves have collected, supplemented as required by external data.

Pillar 2 of the accord requires banks to demonstrate that their management and supervisory systems are satisfactory. Pillar 3 relates to transparency, requiring them to report on their operational risk management.

Solvency II, the EU's regulatory directive for insurers, has adopted the same three pillars. This directive will come into force throughout the EU in 2013.

In November 2007, the US banking agencies approved the US Final Rule for Basel II. Banks will be grouped into the large or internationally active banks that will be required to adopt AMA, those that voluntarily opt-in to AMA, and the rest who will adopt an extended version of the earlier Basel I. A Basel III is in preparation.

Management Tools

The following are approaches to risk management, and in particular to operational risk management (ORM).

- *Risk and Control Self-Assessment (RCSA)*. This is the identification, evaluation and checks on the effectiveness of all significant risks, and the recording and reporting of the results. This may involve the use of questionnaires to establish expert opinion, monitoring key performance indicators (KPIs), form filling, workshops, and independent assessments. External methodologies developed for RCSA, or by supervisory and regulatory

bodies for their own use, can support this.

- *Loss Event Monitoring*. This is the collection and tracking of loss events and near misses, with regular reporting. In some fields, regulators will have specified the events they require to be tracked. Good management will expand on these, particularly in respect of near-miss events which can be predictive of potential loss.
- *Key Risk Indicators (KRIs)*. Tracking and monitoring KRIs can provide early warnings of areas of concern. Doubts stand as to their predictive value.

Figure 2. The risk management cycle.
(Source: Taken with permission from Risk Books [6, p. 228].)

- *Stress and Scenario Testing.* This is the contingency planning for possible adverse events, from payouts occasioned by a badly drawn up contract, to the disaster recovery and business continuity to follow from terrorism or natural catastrophe causing the loss of headquarters, paperwork, processing capacity, and so on. It involves testing impact tolerance and resilience.

CLASSIFYING OPERATIONAL EVENTS

When something is defined only by what it is not, there is always going to be a problem in giving it a taxonomy. A major hindrance prior to Basel II was not only its lack of a constructive definition but also the absence of data. Operational risk losses were generally treated as costs of doing business and allocated to the department where they occurred. As such they were not recorded specifically as operational losses. Even when they were identified as such, if the losses were small, they were not going to contribute significantly to business failure. Post Basel II, data can still be very sparse. An insurer recently had just two oprisk events to show financial supervisors, with another six possible (personal communication).

Operational Risk Loss Event Types in Banking and Insurance

In practice, we would need to identify the operational risk loss events particular to the business activity. A start at this classification can be made by using the seven designated categories of loss events given in Basel II, also adopted in Solvency II, the EU regulations.

- *Internal Fraud (IF).* Losses within the business from fraud, misappropriation of property, unauthorized activity, and circumventing regulations.
- *External Fraud (EF).* Fraudulent claims by an external party, forgery, and hacking damage to systems security.
- *Employment Practices and Workplace Safety (EP and WS).* Organized labor activity, violations of employee health and safety rules, discrimination in employment, and personal injury claims.
- *Clients, Products, and Business Practices (CP and BP).* Unintentional failure or negligence in meeting professional obligations to clients or customers (customer complaints, the suitability of advice, lack of disclosure, including breaches of trust). Flaws in the design or behavior of a product.
- *Damage to Physical Assets (DPA).* Losses from damage to property from natural catastrophes (hurricanes, floods) or man-made events (fires, explosions, terrorism, pollution).
- *Business Disruption and System Failures (BD and SF).* Losses due to hardware or software failure, system design failure, and other infrastructure issues.
- *Execution, Delivery, and Process Management (ED and PM).* Failed transaction processing or management, failed customer/client services (account errors, data entry errors, and incorrect payments), and inadequate monitoring and reporting.

Table 1. The Percentages of Losses of \$10,000 or More for Each Event Type (Taken from the 2005 LDCE in the United States)

Event type	IF	EF	EP and WS	CP and BP	DPA	BD and SF	ED and PM	Other	Total
Losses (%)	3.8	41.8	7.6	9.2	0.7	0.7	35.3	0.8	100

Source: [7].

Table 2. Business Units and Business Lines for International Banking Activities Under Basel II. Percentages of Losses are from the 2005 LDCE

Business unit	Business line	Frequency (%)
Investment banking	• Corporate finance	0.4
	• Trading and sales	7.9
Banking	• Retail banking	65.3
	• Commercial banking	5.5
	• Payment and settlement	4.8
	• Agency services	5.5
Others	• Asset management	2.7
	• Retail brokerage	7.9

Source: [7].

The percentages of losses of \$10,000 or more for each event type, derived from [7, slide 10], the 2005 LDCE in the United States, are shown in Table 1.

Business Lines

Managing operational risk requires a more granular breakdown of the business activities in which the losses occur. Basel II gives eight broad business lines within the banking sector, creating an 8×7 grid of 56 business line/event type cells. Table 2 shows the percentages of losses from each business line from the 2005 LDCE [7, slide 12].

The Operational Risk Consortium Ltd. (ORIC) database of operational risk events, established in 2005 by the Association of British Insurers (ABI), has nearly 2000 events showing losses exceeding £10,000

in the years 2000 to 2008. Insurance has a different set of business lines from banking. The most significant with respect to operational risk are given in Table 3. The event types are those mentioned in the section titled “Operational Risk Loss Event Types in Banking and Insurance.” The data, derived from Selvaggi [8, Fig. 4A, p. 14], give percentages of loss amounts for those business activity/event type cells having at least 4% of the total loss amount.

This information tells little about the actual events. For this we need level 2 and level 3 categories, the seven event types being level 1. To illustrate this, again from the ORIC database, Table 4, derived from Selvaggi [8, Fig. 4B, p. 15], shows the most significant level 2 and level 3 event types in terms of both severity and frequency (values over 4%). It excludes losses arising from the UK’s mis-selling of endowment policies scandal. We note that natural disasters do not feature as significant.

OPERATIONAL RISK MANAGEMENT

Is anything more than common sense needed for ORM? Or so a referee of an application for research funds reported to the awarding panel. We already manage our exposure to operational risk by locking filing cabinets and doors, by using fancy passwords, by installing antivirus software, and so on. It has been argued that it would be sufficient for every employee, from the shop floor through to the main board, to be educated about risk. Of course, one response might be that we would still need to address problems from outsourcing and other subcontracting, and from external events outside the control of the firm. We must remember also that personal attention to risk does not preclude process risk.

A widely accepted approach in risk management is to identify the major risks

Table 3. Business Activity/Event Type Grid Showing Percentages of Loss Amounts (Minimum 4%) in the ORIC Database (2000–2008)

Business activity	Event type				Total
	CP and BP	ED and PM	BD and SF	Others	
Sales and distribution	18.9	6.8		0.7	26.4
Customer service/policy		13.2		2.3	15.5
Accounting/finance		23.4		0.1	23.5
IT			6.0	6.6	12.6
Claims		4.0		1.4	5.4
Underwriting		6.3		0.3	6.6
Others	5.1	11.8	1.4		10.0
Total	24.0	65.5	7.4	11.4	100.0

Source: [8].

Table 4. Level 2 and Level 3 Event Categories from Insurance Losses in ORIC (2000–2008) that Show Loss Amounts and the Frequency of Losses of 4% or More

Level 2 events	Level 3 events	Size (%)	Frequency (%)
Advisory activities	Mis-selling (nonendowment)	13	9
Transaction capture, execution, maintenance	Accounting error	12	
	Inadequate process documentation	8	
	Transaction system error	8	6
	Management information error	7	
	Data entry errors	7	5
	Management failure	5	
	Customer service failure	4	16
Suitability, disclosure, fiduciary Systems	Customer complaints	6	4
	Software	6	
Customer/client account management	Incorrect payment to client/customer		9
	Payment to incorrect client/customer		4
Theft and fraud	Fraudulent claims		4
	Total	76	57

Source: [8].

faced by an organization, measured by their impact in terms of their frequency and severity. In many cases, from a list of 100 operational risks identified as occurring within an organization, no more than 5 or 10 will give rise to the most serious of the loss events and loss amounts. However, the ubiquitous nature of operational risk requires that day-to-day management must use bottom-up as well as top-down risk control. There needs to be an understanding of the risk in all activities. Aggregating losses over business lines and activities would tend to hide the low impact risks behind those having a more dramatic effect. The bottom-up approach is thus a necessary part of seeing the complete risk picture.

Aggregation at each higher level informs management throughout the business.

The perception of the risk needs to match the actual risk. Hazards that have not yet been encountered may not even be considered, and when considered have risks that are hard to calculate.

Operational Risk Management Structure

Figure 3, based closely on Álvarez [6, p. 231], shows the structure of an operational risk management program.

An internal operational loss event register would typically show high impact events at low frequency among events of high frequency but low impact. A financial institution might therefore sort its losses into “expected loss” (EL) to be absorbed

Figure 3. The operational risk management cycle. (Source: Taken with permission from Risk Books [6].)

by earnings, “unexpected loss” (UL) to be covered by risk reserves (so not totally unexpected), and “stress loss” (SL) requiring core capital or risk financing for cover. The “EL” per transaction can easily be embedded in the transaction pricing. It is the rare but extreme stress losses that the institution must be most concerned with. This structure is the basis of the loss data analysis approach to operational risk. Hard decisions need to be made in choosing the EL/UL and UL/SL boundaries. This latter would often be the maximum probable loss. Besides these, a threshold “petty cash” limit is needed to set a minimum loss for recording it as an operational loss. Loss events with recovery and other near-miss events also need to be in the internal database for the information they carry. The threshold and boundaries are set separately for each business activity/event type category.

External Data

In addition to the management tools mentioned in the section titled “Management Tools”, operational risk management will often need to supplement their internally collected data. The shortage of in-house oprisk data, particularly large loss events that

would have a major influence in estimating reserve funds to cover a major loss should it occur, is such that data publicly available or from commercial or consortia databases will need to be explored.

Insurance

Transferring operational risk through insurance is problematic as a risk management tool [3, p. 187].

For example:

- Blanket cover would not be available, leaving unforeseen events uncovered.
- Exclusions could deny payment. Similarly, delays in payment, possibly for years if legal proceedings take place, could put firms at risk.
- The absence of sufficient and appropriate data would make pricing the risk difficult.
- Risk transfer may lead to moral hazard, the abandonment of responsibility for risk management.

Most importantly perhaps is that, although insurance is a means of mitigating the consequence of operational risk losses, it does nothing to enhance control of the risk itself [9, pp. 11 and 259–260].

MODELING OPERATIONAL RISK

The Marked Point Process

The appropriate structure for modeling oprisk events is that of the *marked point process*. Along the time line (the x axis) we have points representing the times of occurrence of the events. We attach marks to each of these points. These are labels representing information about the events (see the section titled “Database Acquisition”). In practice, the first label is the loss size z , which can be represented by a vertical spike at its time point t , its height being proportional to the size (with the y axis showing the scale). The second label is a code i for the i th business activity, and a third with a code j for the j th event type. We are thus coding each point by a (t, z, i, j) .

The statistical modeling has to identify the probability structure for these four-dimensional descriptors. We can study each business line separately and compare its losses and their occurrence times with those for any other business line, or even the rest of the business lines; and similarly for the event types, and every business line/event type combination. This structure can be visualized as the superposition on the time line of processes for each business line/event type combination (i, j) separately. The interaction between the interval processes of gaps between events and their sizes can also be studied.

We have here a rich mixture to model. In practice, we would need substantial amounts of data to provide more than just basic statistical properties. In the section titled “Example: Fitting GEV and GPD,” we model data from a single activity and event type and fit only a loss severity probability distribution.

MEASURING OPERATIONAL RISK

Basel [1, para. 665] requires that the internal measurement system of banks adopting the advanced measurement approaches “must reasonably estimate unexpected losses based on the combined use of internal and

relevant external loss data, scenario analysis, and bank-specific business environment and internal control factors (BEICF).”

Using the prudent amount of risk capital allocation as a proxy for risk, and obtaining this measure by modeling collected loss data, may seem to satisfy the need for objectivity. It seems to avoid the subjective interpretation of risk indicators and expert opinion.

In practice, the quality of data and of its collection, the appropriateness of the model choice, the risk modeling of potential high impact outcomes that have not happened, the very shortage of data on those that have, and assessing and aggregating the loss from a major event, or the potential loss from a near miss, the dynamics of risk management practices making historic data out of date, the use of external data which cannot match the loss profile of the business, all of these point to loss data analysis being a highly subjective approach to quantitative measurement of operational risk.

Despite this, the act of establishing a price for risk highlights risky activities, as well as those held back because of exaggerated risk assessment. It can be used as the basis of cost–benefit analysis in capital allocation. Further, loss data modeling allows for predictions and forecasting, for identifying correlations between business lines and between event types, for scenario analysis, stress testing, benchmarking, validation, backtesting, and so on.

There is no true answer, and no methodology on its own can provide it. Multiple approaches should be used, both qualitative and quantitative. The objective must be to assist management in acquiring a sensitivity to data, and in its interpretation for use in decision making.

Database Acquisition

A loss event register is vital to understanding the risk environment. The data entered should show more than just the loss amounts. The records should show for each loss event

- a reference number for the event;
- the level 2 business line code;
- the level 3 business line code;

- the event type;
- where it occurred;
- when it occurred;
- when it was discovered;
- the gross loss amount;
- amount of any direct recovery;
- amount of any indirect recovery;
- if a near-miss event, an estimate of the potential loss amount;
- reference numbers of related events;
- a short narrative, to include, if needed, proposed corrective action. (*Source*: [3, p. 111; 10].)

External Data

Basel II requires internationally active banks to have a systematic process for determining as to when external data must be used and how to make use of the data (“the use test”), for example, scaling, qualitative adjustments, or improving scenario analysis. The accuracy and completeness of external data have to be validated.

Scenario analysis enables an organization to consider responses. However, merging extreme scenario data with actual loss data corrupts those data and distorts the loss distribution, and could lead to higher capital charges than might otherwise be the case.

External loss data are available from industry consortia and commercial sources. Reference has already been made in the sections titled “Operational Risk Events Make Headlines” and “Business Lines” to the OpVar and ORIC databases.

The Operational Riskdata eXchange (ORX) Association is a well-established database of operational risk events in banking. The not-for-profit consortium collects data quarterly from its 54 member banks from 15 countries, using a standard format. It has attempted to establish loss data standards for the secure exchange of high-quality anonymous oprisk loss data. The standard format of ORX informed the list proposed in the section titled “Database Acquisition” for internal database acquisition. In March 2010, ORX reported that it has more than

180,000 losses, each at least €20,000, and totaling more than €47 billion [10].

There are also national banking databases, and those using publicly available information from the press and trade publications. Insurance companies have their own claims registers, with accurate records of amounts paid in settlement.

The Small Sample Problem

An extreme loss in a small sample is over-representative of its 1-in-a-1000 year or 1-in-a-10,000 year chance, yet underrepresented if not observed. The largest losses are generally overly influential in any fitted model. So, we must conclude that fitting a small data set cannot truly represent the loss process whatever model is used.

Basic to statistical practice is reporting on the quality of any estimate. With only a small data sample of oprisk losses, with none very large, we have no way of reporting an accurate value of a loss that would be seen only once in a 1000 years. It is a well-understood principle that any statistical inferences about models in regions far outside the range of the available data should be treated with caution. In carrying out loss data analysis we are operating outside our statistical comfort zone.

Probability Modelling of Loss Data

The Gaussian (normal distribution) model of much of statistical inference is inadequate for loss data. Even a truncated normal distribution that excludes negative and small positive values gives too little chance to large and very large losses. The lognormal distribution has been used instead historically in econometrics theory, and the Weibull in reliability modeling.

Two models that can allow rare large observations come from extreme value theory. The generalized extreme value (GEV) distribution and the generalized Pareto distribution (GPD) are the limit distributions as sample sizes increase to infinity. Environmental studies (hydrology, pollution, sea defences, etc.) already use them. Each of them has parameters μ giving location, σ scale, and ξ shape, which we vary to obtain a good fit. The location μ and scale σ are

Figure 4. The probability densities of GEV (0.70, 230, 100) (line) and GPD (0.70, 150, 125) (dashes).

Table 5. Penalties Imposed by Financial Regulators (In Thousands of US Dollars)

3822	907	735	556	423	395	302	260	248	220	204	193	180	160	150

Source: [12].

not to be identified with the population mean and standard deviation. For the GPD, μ is the lower bound of the range. Figure 4 shows the form of their respective probability density functions. Models with four and more parameters, such as Tukey's g-and-h class of distributions, are also gaining users: but they do require more data than is usually available. They have though been seen to capture the loss distribution of aggregated firm-wide losses. Readers are referred to Young and Coleman [3] for plots and properties of these and other models.

Example: Fitting GEV and GPD. This section follows the analysis in Young and Coleman [3, pp. 399–403], summarized in Coleman [11], for fitting the 75 losses given in Cruz [12, p. 83]. In Table 5, these data have been ordered and rounded to the nearest \$1000.

Figure 5 shows the sample cumulative distribution function (the observed proportion of values less than x) shown as steps, together with four fitted cumulative distribution functions (the height y is the probability of obtaining a future value less than x). The range of observation is (143, 3822). Figure 5 shows a good fit in each case. Table 6 shows

the values of four fitted models, and some large quantile values for each of them (the x values for given y values). For example, the 99th percentile $Q(0.99)$ is at a loss value of 3663 for the first model. The others are at 2794, 4457, and 2605. The 99.9th percentiles range from 7595 to 22,452. This $Q(0.999)$ is to be the basis of regulatory charging in banking, with $Q(0.995)$ for insurers. Estimation far outside a data set is always fraught. This can lead to significant errors in high quantile estimation. Quantiles give no information about how big a future loss larger than $Q(p)$ is likely to be. A measure used for this is the *mean excess*, also called *conditional value-at-risk* (*CVaR*). This computes the mean over the values greater than $Q(p)$ of the fitted model probability.

A simulation study of GPD (0.70, 150, 125) gave an approximate 95% confidence interval for $Q(0.999)$ of (5200, 9990).

A simulation of 4000 values from GEV(0.53, 230, 130) gave the estimates (0.50, 227, 126) for its parameters, emphasizing the need for large data sets.

The computations were made using Academic Xtremes, a computer package that accompanies Reiss and Thomas [13].

Frequency Modeling

Standard statistical methods can be used to fit Poisson or negative binomial probability distributions to frequency counts. Experience shows that the daily, weekly, or monthly frequencies of loss events tend to occur in ways that cannot be fitted well by either of these models.

Combining Internal and External Data

When data from an external database are combined with an in-house data set, the former are relocated and scaled to match the latter. Then, we adopt the location and scale of the internal data. Finally, we check the

threshold used for the internal data against the new threshold for the relocated and rescaled external data, and set the larger of the two as the new threshold, eliminating all data points that fall below.

This is illustrated in Giacometti *et al.* [14, p. 7], where we see that it can lead to strange statistical results if the location and scale metrics are not chosen appropriately. A table shows a mean of pooled data having a mean smaller than the mean of both the internal and the external data. The same happens to the medians. Elsewhere another pooling shows skewness and a kurtosis of pooled data being larger than those of the separate

sets. We should perhaps be seeking a better standardization of operational risk loss data. In Reiss and Thomas [13], a logarithmic transformation of the data is taken prior to standardization. This corresponds to fitting a lognormal probability distribution to the data, but it did not entirely rectify the paradoxical result. A two-parameter extreme value theory model such as the standard Gumbel distribution should be a better choice for standardization. This choice has been applied in an environmental context relating different measures of air pollution [15].

CONCLUDING REMARKS

With risk being found in every enterprise, why does finance have such a prominent role in the study of it? Or does it? The theory of probability and statistics grew out of calculation of the odds in gambling. Knowing its true value gave an edge to any gambler. The mathematics was extended to set the price for life insurance, to determine the premium that should be charged for assuming the risk.

The financial services regulators make explicit in their rules the requirements of modeling, measuring, and using the results of the exercise. There are no prescriptive rules for the models that are to be used. The finance industry is still searching for the best practice. This is driving efforts at finding robust processes for operational risk, and evaluating methodologies for it. We must wait and see what emerges.

OPERATIONS RESEARCH AND MANAGEMENT SCIENCE IN FIRE SAFETY

JOHN M. WATTS, JR
Fire Safety Institute,
Middlebury,
Vermont

Fire safety incorporates many different types of problems: sociological, technical, and managerial. In 1974, The Lanchester Prize, the most prestigious award offered by the Operations Research Society of America, went to the authors of a book describing how to reposition available fire companies in response to changing patterns of fire alarms [1]. This work was part of the comprehensive undertaking of the New York City/Rand (NYC/RAND) Institute to study the complexities, uncertainties, and multiple variables in the urban policy-making environment. Fire service deployment and emergency response remain a major area of application of operations research/management science (OR/MS) and are described in a separate article in this encyclopedia [2]. The broader concept of fire safety deals with encompassing aspects, such as combustibility of fuels, building construction, automatic detection and suppression systems, and occupant egress, for which the local fire department is only one component. The following are the types of OR/MS methods that have been employed among others:

- decision analysis,
- simulation,
- stochastic processes,
- networks,
- statistics, and
- economics.

WHAT IS FIRE SAFETY?

Fire has been described as one of the least understood common phenomena. Other animals have been found to use language

and tools, but use of fire distinguishes *Homo Sapiens* among that species that exist on the earth. Along with this use is its misuse, which constitutes a significant loss of life and property, mission failure, environmental destruction, and damage to our culture.

Aspects of fire safety include the chemi-cophysical nature of unwanted combustion, a weakly defined scientific process that can occur and be affected by a myriad of environmental conditions including ignition sources, types of combustibles, configurations of the fuel, and space in which it is burning, proximity to people and valuables, and the various response systems of fire detection and suppression.

Anyone looking to gain insight to the problem would do well to read the Scientific American book, *Fire*, by John Lyons [3], which provides an excellent description of the phenomenon and its implications to our society. The two-volume *Fire Protection Handbook*, published by the National Fire Protection Association [4], is an extensive compendium of basic approaches to fire safety in many aspects. The *Handbook of Fire Protection Engineering*, produced by the Society of Fire Protection Engineers, describes technical approaches to fire and fire safety that have evolved from our better understanding of the concept of fire safety science [5]. Section 5 of this Handbook covers the area of fire risk analysis, which employs some typical OR/MS approaches, including applications in health care, transportation, and consumer products.

While as early as 1965 Jarrett [6] identified aspects of fire safety that are amenable to OR/MS techniques, applications have been piecemeal. With the notable exception of the NYC/RAND project identified above, there has been little concerted effort to deal with fire safety in an operations research or management science approach. Areas of interest beyond municipal fire service deployment include wildland fires, process industries, and fire safety in buildings. This article introduces concepts of these applications and focuses on the mostchallenging issue: fire

safety in buildings.

WILDLAND FIRES

Among the more dramatic yet approachable fire safety problems are forest fires—or in the modern jargon, wildland fires—and in particular the interface of fire-prone wildland and encroachment of built environments, for example, the “urban–wildland interface.” Among the distinctions of this class of fires are a relatively homogenous “fuel load” (combustibles available to burn), a relatively limited (e.g., natural) variety of topography, and a major dependence on weather.

It is interesting to note that the third edition of Quade’s book, *Analysis for Public Decisions* [7], uses wildland fire [8] as an example of OR/MS modeling. The evolution of such models, within the US Forest Service and worldwide, has progressed measurably. An invited lecture was given by Frank Albini at the fifth triennial symposium of the International Association for Fire Safety Science [9]. This is an excellent introduction to the level of sophistication of current wildland fire models that integrate physicochemical aspects of fire spread into simulations of fire control. Applicable OR/MS methods also include allocation methods.

The significance of dealing with wildland fires has substantially increased as the extent of the wildland–urban interface has increased and greater incidence and severity seem correlated with global climate change. Significant research efforts are in progress in Australia and Southern Europe, parts of the world that have recently experienced devastating wildland fire events.

A prolific author of readable yet technical information on the subject is Pyne [10]. For a more complete description of the events and issues in the United States, the reader is referred to *The Wild Fire Reader: A Century of Failed Policies* [11]. A literary work worth reading is *Young Men and Fire* by Norman Maclean [12]. The first half of this book is a stirring tale of a wildland fire that occurred in 1947. The second half details the author’s 1990s investigation of the events that led to the deaths of 12 smokejumpers, which includes modern methods of wildland

fire modeling. It could be construed as an example of applied OR/MS.

INDUSTRIAL FIRE SAFETY

Under the guise of “process safety,” there are many OR/MS techniques that have been adapted to fire problems in the areas of aerospace industry, petrochemical facilities, and nuclear power generation plants. Some of these are described in the aforementioned *SFPE Handbook of Fire Protection Engineering* [5], and include

- probability models, such as stochastic fire growth;
- statistical models, such as extreme value;
- mathematical programming;
- cost–benefit analysis;
- networks such as fault trees; and
- reliability theory.

“System safety” techniques such as fault tree analysis evolved with the aerospace program where predictive models were needed in the absence of experience. See, for example, the *Systems Safety Handbook* [13]. The applicability of this approach was enhanced by the Rasmussen report on safety of nuclear facilities [14], also known as *WASH 1400*. This trend continued with standards such as MIL-STD 882C [15] and publications from the Center for Chemical Process Safety [16,17]. These techniques are not exclusively specific to fire but cover a multitude of potential safety hazards as well.

Many industry OR/MS safety system studies focus on reliability programs. The book *What Every Engineer Should Know about Reliability and Risk Analysis* uses a fire safety system as an example application [18, pp. 318–328].

Industry and insurance have motivated some of the better applications of OR/MS to fire safety economics. This can be traced back as least as far as Mandelbrot’s 1964 article in *Operations Research* [19]. The paper by Shpilberg and Neufville that appeared in *Fire Technology* in 1974 [20] is a classic example of a decision tree and utility theory approach to fire safety. It relates hardware alternatives for fire protection and insurance

deductibles in a decision tree model. This work and similar approaches are discussed in the book *Fire Protection Economics* by Ramachandran [21]. This is perhaps the only monograph that specifically addresses fire safety decision-making techniques.

Economic issues involving very tall buildings have taken on multifarious aspects that were formerly associated only with the more complex systems of industrial situations. New construction techniques, security concerns, and some deep pockets have created need for modeling the economics of alternative approaches to hazard mitigation. The National Institute for Standards and Technology (NIST) has recently produced and distributed a computer model to address these issues [22].

FIRE SAFETY IN BUILDINGS

The issues associated with fire safety in buildings fall within a class of problems that have many unexpected and little understood characteristics of a “complex system,” defined as a high order, multiple loop, nonlinear feedback structure. Feedback structure is common to all types of decisions, but feedback in complex systems has some special characteristics.

“Order” of a system refers to the number of state variables that define the system: for example, fire temperature, heat release, smoke concentration, spatial geometry, occupant density, and location. Complexity increases rapidly with the order of the system, and in fire safety we have a myriad of factors that affect the outcome of a fire scenario.

Complex systems have multiple feedback loops. Primary feedback loops in building fires are thermal energy of the fire, smoke, and toxic products of combustion, and the interaction of these thermodynamic conditions with people in the building. The evolution of combustion physics and computational fluid dynamics (CFD) modeling is moving us toward better understanding of mass (smoke and toxic gasses) transport in different types of buildings.

Most mathematics deals with linear processes. Fire and human behavior exhibit a great deal of nonlinearity. Multiple loop

realignment along nonlinear functions makes the complex system highly insensitive to most system parameters and thus resistant to efforts to change system behavior. In fire safety, we do not yet have a solid feel for the significance of the observed nonlinearity or how to deal with it.

Constraints on the fire safety system are often of a political nature in addition to fixed architectural or physical restraints. There are limitations imposed by construction practices and fire protection hardware technology. And marketing influences may come into play. But the most significant constraint is the incoherent agglomeration safety standards known as building codes. Building codes, along with other fire safety codes and regulations, are intended to be minimum standards for effective fire safety. However, as was demonstrated by Howard Emmons, the eminent Harvard professor of mechanical engineering, over 40 years ago [23], aspects of these requirements, when subject to scientific scrutiny, are found to be unnecessarily overbearing and hence may constrain fire safety rather than promote it.

One way to approach the analysis of complex systems is by decomposition into component parts. By understanding the behavior of simpler subsystems, we can gain insight into the expected behavior of the complex system. As this decomposition continues into smaller and smaller components, the diversity of knowledge brought to bear expands greatly. This is reflected in the wide range of details that have been considered in dealing with fire safety. But reality is not rigidly compartmentalized. We risk further loss of control if the complex system is not dealt with in its totality. This is substantially the current state of the art of building fire safety. The synthesis step is still missing.

Most readers of this article would have their scientific sensibilities offended by the fire safety codes and standards used to dictate building construction and occupancy. Inroads to more systemic fire safety evaluation have evolved in the last decade under the sobriquet of “performance” engineering, for example, Society of Fire Protection Engineers [24]. While still in a neonatal stage, the concept of building design based on fire performance evaluation is encouraging.

FIRE SAFETY IN BUILDINGS: AN APPLICATION

Fire risk indexing is an aggregation of system variables into a single index to reflect an ordinal evaluation of fire safety in a building. The approach uses many tools and techniques of OR/MS, including decision analysis, Delphi, multiattribute evaluation, analytic hierarchic process (AHP), scaling techniques, utility theory, hierarchical methods, decision tables, and careful thought. The following description and process is adapted from Chapter 13 in the book *Evaluation of Fire Safety* [25].

In general, a fire risk index assigns values to selected attributes based on professional judgment and experience. The selected variables represent both positive and negative fire safety features and the assigned values are then operated on by some combination of arithmetic functions to arrive at a single value or index. This value can be compared with other similar assessments or to a standard.

Fire risk indexing is not a substitute for detailed theoretic fire safety evaluation. It is a planning tool useful for screening, ranking, and setting priorities. Fire risk indexing systems come in a large variety of formats and with a broad spectrum of purposes. Reviews of example fire risk indexes may be found in the *SFPE Handbook of Fire Protection Engineering* [26].

As has been pointed out in this article, fire safety evaluation involves the analysis of many complex factors that are difficult to assess in a uniform and consistent way. Defensibility, both internally and externally, is one of the strongest assets of a scientifically constructed index system. Internal defensibility provides management with justification for fire safety policies and expenditures. It facilitates the allocation of limited resources among fire and other risks. External justification of priority-setting is important in litigation and in dealing with regulatory agencies.

Fire risk indexing is a heuristic model of fire safety. It is a process of modeling and scoring fire hazard and exposure factors to produce a rapid and simple estimate of

comparative evaluation. The process heuristically relates known fire safety attributes that have varying degrees of accuracy in their measurement. The distinct advantage is a complete model that does not depend solely on assumptions about unsubstantiated physical processes.

For many situations where a quantitative fire safety evaluation is desirable, an in-depth theoretic analysis may not be cost effective or appropriate. This could be the fundamental case where great sophistication is not required, where prioritization is the principal objective, or where it is necessary to institutionalize an approach to fire safety evaluation for a wide base of use. The objective of fire risk indexing is to sacrifice details and individual features for the sake of making the assessment easier. Information should be reduced to a single score even in the most complex applications. OR/MS techniques have been espoused to combine technical, economic, and sociopolitical factors.

Because of our limited phenomenological knowledge, the accuracy demanded for a fire safety evaluation is different from other engineering purposes. Often, establishing an order of magnitude will suffice. Time and resource expenditure increases as the depth of analysis is increased. In an age where resources are scarce, and efficiency is prized, maximizing the utility of a fire risk indexing approach to fire safety evaluation is clearly desirable for the many situations where the evaluation of fire safety is fundamental.

Perhaps the most common implicit justification of fire risk indexing is the need for a simplistic process of fire safety evaluation. In most applications, the target of fire risk indexing is a broad class of products or facilities for which a detailed fire risk analysis of each individual case is not feasible. Fire risk indexing has an appeal to administrators charged with risk management decision-making responsibilities but who may be unfamiliar with the details and mechanics of the fire risk assessment process. Widespread implementation of a generalized approach to fire risk is contingent on its appeal to a broad class of users including architects, building officials, and property managers.

Multiattribute Evaluation

By nature of the circumstances, fire safety decisions often have to be made under conditions where the data are sparse and uncertain. The technical parameters of fire safety evaluation are very complex and normally involve a network of interacting components, the interactions generally being nonlinear and multidimensional. However, complexity and sparseness of data do not preclude useful and valid approaches. Such circumstances are not unusual in decision making in business or other risk venues and, unless such problems are addressed, developments that could be useful to society may be inhibited. The space program illustrates how success can be achieved when there is little relevant data. One applicable approach to fire safety evaluation is multiattribute evaluation.

The importance of multiattribute evaluation to fire safety is that there are several well-used and accepted approaches to fire risk indexing that do not have any credible structure to their development. Hence, there is no transparency or technical validity, yet they are used to make life threatening decisions.

As implied above, fire safety decisions require more than one attribute to capture all relevant aspects of the consequences. If the attributes for a decision problem are $x_1, x_2, x_3, \dots, x_n$, then an evaluation function $E(x_1, x_2, x_3, \dots, x_n)$ needs to be determined over these measures in order to conduct a performance assessment. However, determining an appropriate evaluation function over multiple performance measures is a complex problem. Subjective attribute values must be elicited by asking questions, and it seems difficult to answer questions that will directly determine an n -dimensional function.

If trade-offs among the attributes do not depend on the levels of the remaining attributes, then a single measure of the overall outcome of a system is given by

$$E(x_1, \dots, x_i, \dots, x_n) = \sum_{i=1}^n w_i R_i(x_i),$$

where w_i are weighting constants greater than zero and $R_i(x_i)$ are normalizing functions of the attributes.

Evaluation of fire safety can be a difficult endeavor. Many, sometimes conflicting, attributes must be juggled simultaneously. The field of OR/MS has long dealt with this type of problem. There is a large body of literature on the subject of multiattribute evaluation, also known variously as *multiattribute decision analysis*, *multicriteria decision making*, and *multiattribute utility theory*. These methods apply to problems where a decision maker must evaluate, rank, or classify alternatives characterized by two or more relevant attributes. Summaries and descriptions of the principal methods are in other articles in this encyclopedia.

Multiattribute evaluation begins with the generation of attributes that provide a means of evaluating goal achievements. These attributes, referred to in some applications as parameters, elements, factors, variables, and so on, identify the ingredients of fire safety.

Fire safety attributes are components of fire risk that are quantitatively determinable by direct or indirect measurement or estimation. They are intended to represent factors that account for an acceptably large portion of the total fire risk. Usually they are not directly measurable. This is especially true for existing buildings where only limited information is readily available. Thus, attributes may be either quantitative or qualitative, and both types of attributes are very important. Selection of attributes should result in a set that is nonconflicting, coherent, and logical.

ATTRIBUTE GENERATION

Fire safety is a complex system with an inordinately large number of factors that may affect it. These can range from ignitability of personal clothing to availability of a heliport for evacuation. Computational and cognitive feasibility limit consideration to only a relatively small number of these variables.

It is intuitively appealing to postulate that safety from fire is a Paretian phenomenon in that a relatively small number of attributes account for most of the problem. This is supported by general fire loss figures, which suggest that a small number of factors are

associated with a large proportion of fire deaths. It is necessary, then, to identify as attributes some defensible combination of factors that account for an acceptable portion of the fire risk. A desirable list of attributes should be as follows:

- *Complete and exhaustive.* That is, all important attributes should be represented.
- *Mutually exclusive.* Independence of the attributes facilitates evaluation of trade-offs.
- *Restricted to highest degree of importance.* Lower level criteria may be part of attribute rating discussed later in this section.

A study of fire safety effectiveness statements conducted for the US Fire Administration focused on logical and reproducible means of identifying key life safety variables [27]. Following is the list of 19 key life safety variables or attributes identified as a result of this study. The attributes are placed into four groupings for convenience and clarity.

Fire development

- Amount of combustibles
- Rate of heat release
- Toxicity of combustion products
- Obscuration by smoke

Fire spread

- Fire resistance of structural members
- Fire/smoke barriers
- Fire resistance of vertical shafts
- Isolation of hazardous functions/materials

Fire control

- Automatic extinguishing system
- Automatic smoke control
- Systems maintenance
- Suppression by in-house staff
- Suppression by municipal fire department

Egress

- Exit way dimensions

- Remoteness and independence of exits
- Height of building
- Automatic fire detection and alarm system
- Physiological/psychological condition of occupants

This detailed process is not typical for most fire risk indexing systems. Selection of attributes is usually more arbitrary, with correspondingly disparate results. Where the subject of attribute generation is addressed, it often involves an adapted Delphi exercise. Operational considerations of Delphi applications to multiattribute evaluation in fire safety have been addressed in the literature. Donegan [28] discuss Delphi briefly among other approaches to subjective measurement in fire protection engineering. Development of attributes relies heavily on intuition and subjective judgment. In the final analysis, it is most important that the evaluation vector include only those attributes that significantly vary among buildings and for which the variation is considered meaningful.

Attribute Weighting

Not all fire safety attributes are equally important. The role of weight serves to express the importance of each attribute compared with the others. Hence the assignment of weights is a key component of multiattribute evaluation. Although assigning weights by an ordinal scale is usually easier, most multiattribute evaluation methods require cardinal weights. The attribute weights are generally normalized to sum to one, that is, if y_i is the raw weight of attribute I , then

$$w_i = \frac{y_i}{\sum_{i=1}^n y_i}$$

and

$$\sum_{i=1}^n w_i = 1.$$

This produces a vector of n weights given by

$$W = [w_1, \dots, w_i, \dots, w_n],$$

where w_i is the resultant weight assigned to the i th attribute.

This relative importance of attributes is defined to be constant across building evaluations. There are many weight assessment techniques used in multiattribute evaluation. Generally, hierarchical methods have been found effective in fire safety evaluation.

Attribute Ratings

Each attribute weight represents a specific relative importance that is universal for all facilities within the scope of the evaluation method. Individual buildings will vary in the degree to which attributes exist or occur in a space. Attribute ratings or grades are a measure of the intensity level or degree of danger or security afforded by the attribute in a particular application.

The selected attributes may be either quantitative or qualitative. Because both types of attributes are very important, we need a method that accounts for attributes of a general nature. Qualitative attributes may be impractical, impossible, or too costly to measure directly. Likert scaling is most often used to empirically capture the essential meaning of the attribute and develop a scale upon which a surrogate measure or rating can be based.

Quantitative attributes are readily measured or quantified but may require judgment to convert into a compensatory measure. Each quantitative attribute typically has a different unit of measurement. Since multiattribute evaluation scoring generally requires a homogenous data type, data transformation techniques become necessary. Quantitative attribute ratings must be normalized to a scale that is common to all attributes.

Likert Scaling

Scaling and scale construction are of central concern in the measurement of any phenomena. This includes objective conditions as well as subjective states. Scaling identifies each individual object so that valid and reliable differences among objects can be represented.

No scaling model has more intuitive appeal than the Likert scale. Likert scaling rates attributes as 1, 2, 3, 4, or 5, reading

from unfavorable to favorable. A 5-point Likert scale is used predominantly, but a more detailed scale such as a 7-point or 10-point scale can also be used if its application does not create undue cognitive stress.

There are three underlying assumptions of Likert scaling:

- Each item is monotonically related to the underlying latent dimension continuum, that is, there is no obvious discontinuity or reversal of slope.
- The sum of the item scores is monotonic (and approximately linear) with respect to the dimension measured.
- The items as a group measure only the dimension sought. In other words, all items to be linearly combined should be related only to a single common factor. The sum of these items is expected to contain all the important information contained in the individual items.

Only this last assumption tends to be somewhat problematic. It is difficult to decide conclusively that the items as a whole are measuring only a single phenomenon.

In an experiment on Delphi methodology, the equivalence of three simple scaling techniques was examined and it was concluded that for practical purposes the results could be accepted as an interval scale. The experiment showed that Likert scales used in Delphi exercises have the equal difference property and therefore combinatorial calculations are appropriate. The intervals between scores on a Likert scale are meaningful but ratios of scores are not interpretable.

Normalization of Data

Typically, each quantitative attribute has a different unit of measurement. In order to attain the compensatory trade-offs that are an essential characteristic of multiattribute evaluation, commensurable attribute units are necessary. Attribute ratings are therefore normalized to eliminate computational problems caused by differing measurement units in the evaluation vector. Thus, we need to construct or adopt a normalizing function $R_i(x_i)$ for each attribute i .

Fire safety attributes may be beneficial, detrimental, or nonmonotonic. Beneficial attributes offer monotonically increasing utility: the greater the attribute value, the more its preference, for example, fire resistance. Detrimental attributes are monotonically decreasing in utility: the greater the attribute value the less its preference, for example, rate of heat release. Nonmonotonic fire safety attributes are uncommon. One, perhaps unique, example is floor level, where, for life safety, grade level is preferred over stories above or below grade.

The most common form of normalization is linear. For beneficial attributes, the normalized rating of attribute i , r_i , is given by

$$r_i = \frac{x_i - x_i^\vee}{x_i^\wedge - x_i^\vee},$$

where $x_i^\wedge$ is the ceiling or maximum possible value of x_i , and $x_i^\vee$ is the floor or smallest possible value of x_i . Thus the expression $x_i^\wedge - x_i^\vee$ is the range of all possible values of attribute x_i . If, as often happens, $x_i^\vee = 0$, then the normalized rating is given by the ratio of the attribute value to the maximum value, $r_i = x_i/x_i^\wedge$. The resultant ratings have the characteristic that $0 \leq r_i \leq 1$ and the attribute is more favorable as r_i approaches 1.

The linear normalized rating of a detrimental attribute i is given by

$$r_i = \frac{\hat{x}_i - x_i}{\hat{x}_i - x_i^\vee}.$$

Again, the resultant ratings have the characteristic that $0 \leq r_i \leq 1$ and have been adjusted to be consistent with beneficial attributes so that the attribute is more favorable as r_i approaches 1.

There are statistical procedures for normalizing nonmonotonic attributes, but they are typically not necessary in fire safety evaluation. Where quantitative and qualitative attributes are mixed, the normalized ratings should be multiplied by the modulus of the Likert scale used for the qualitative attributes. For example, if a 5-point Likert scale is used for qualitative data, then the normalized ratings should be multiplied by

5. This is essential to maintain the compensatory capability of the scoring method.

Decision Tables

Fire safety attribute rating can be facilitated by partitioning the attributes into measurable constituent parts. Usually, these parts will be directly measurable survey items. Sometimes, there may also be intermediate subattributes. A survey item is a measurable feature of a building or building space that serves as a constituent part of one or more attributes or subattributes.

Decision tables are commonly used in decision analysis and documentation. Their purpose is to provide orderly representation of information flow in elementary decisions. While such decisions can appear simple by relative comparison, their underlying logic may often be complex. The tabular approach is used to express decision logic in a way that encourages reduction of a problem to its simplest form by arranging and presenting logical alternatives under various conditions. Decision tables have been shown to present a useful logic for using survey items to develop ratings for fire safety attributes [29]. Three properties of decision tables that contribute to their effectiveness in fire safety evaluation are the following:

- Disciplined way to rate fire safety attributes using data on survey items.
- Concise and standardized documentation of the detailed design of a fire risk index.
- Simple transition to computerized application.

Analytic Hierarchy Process (AHP)

Ratings for fire safety attributes can also be developed using pairwise comparisons and the AHP. AHP has been widely reviewed and applied in the literature and its use is supported by several commercially available user-friendly software packages. In this approach, the relative importance of each survey item or subattribute is determined by setting up a square matrix A and making pairwise comparisons. Relative importance of each item can then be calculated

from the matrix using any of several methods. The best known and most supported by commercial software is the eigenvalue prioritization method.

When using pairwise comparisons and AHP, the number of fire safety subattributes or survey items for each attribute should be limited to around 7. This number is congruous with the theory that 7 ± 2 represents the greatest amount of information that an observer can give us about an object from an absolute judgment [30]. If the practical range of the attribute ratings is not known, AHP can be subject to distortion and rank reversal, although this is seldom the case in fire safety evaluation.

Scoring

A multiattribute evaluation may be viewed as a vector of attributes. The transformation of a vector to an appropriate scalar value is the purpose of the fire risk index, that is, formulating an index to represent the effectiveness of the system. In fire safety, we do not yet have a thorough understanding of the functional relationships among components, so simple heuristic scoring techniques are used.

Additive weighting is the most widely used method in fire risk indexing. The score is determined by adding the contribution from each attribute. Since two items with different measurement units cannot be added, a common numerical scaling system such as normalization, discussed in the previous section, is required to permit addition among attribute values. The total score for each evaluation then can be computed by multiplying the comparable rating for each attribute by the importance weight assigned to the attribute and then summing these products over all the attributes. Formally, the evaluation score S in the additive weight method can be expressed as

$$S = \sum_{i=1}^n w_i r_i,$$

where w_i is the weight of attribute i and r_i is the normalized rating of attribute i . Thus, the numeric evaluation is calculated as the scalar product of the weighting vector and rating vector of the attributes.

The underlying assumption of additive weighting is that attributes are preferentially independent. Less formally, this means that the contribution of an individual attribute to the total (multiattribute) score is independent of other attribute values. Therefore, preferences regarding the value of one attribute are not influenced in any way by the values of the other attributes. Fortunately, studies show that additive weighting yields extremely close approximations to “real” value functions even when independence among attributes does not exactly hold.

Additive weighting permits very lenient assumptions about individual components of a scale. This suggests that, because each item may contain considerable measurement error or specificity, the importance of this additive model is that it does not take any particular item very seriously. Additive weighting also assumes that the characteristic weights are proportional to the relative value of a unit change in each attribute’s value function. This is what makes the fire risk index compensatory.

Application Observations

Fire risk indexing has gained some acceptance because of its high utility and relative ease of application. Fire safety evaluation involves a large number of multifarious factors that are hard to assess in a uniform and consistent way. Analysis of such a complex system is difficult but not impossible as evidenced by activities in the fields of nuclear safety and environmental protection. Detailed risk assessment can be an expensive and labor-intensive process and there is considerable scope for improving the presentation of results. Fire risk indexing can provide a cost-effective means of fire safety evaluation that is sufficient in both utility and validity.

For analytical and procedural simplicity, common practice neglects both uncertainties and imprecision inherent in the evaluation vector data and in the additional elicited information about the attributes and objects. Neglect of uncertainty occurs when uncertain values are represented by their expected values rather than by probability distributions. Neglect of imprecision occurs when

ratings such as “good” and “bad” are converted to scalar numbers rather than ranges. All applications to fire safety follow this practice. Chance or random error is involved in any type of measurement. However, as Nunnally [31, p. 67] observes, “this unreliability averages out when scores on numerous items are summed to obtain a total score, which then frequently is highly reliable.”

Fire risk indexing tries to obtain a meaningful index from multidimensional data to evaluate fire safety. They are relatively simple models that do not rely exclusively on demonstrated principles of fire dynamics and OR/MS. But their credibility is enhanced to the extent that they do employ such principles.

CONCLUSION

Over its relatively short life, OR/MS has become known for the use and development of quantitative modeling tools and techniques such as described elsewhere in this encyclopedia. All of these are applicable to issues of fire safety. But, while application and refinement of algorithmic methods is a visible and useful component of OR/MS, it is the tip of the problem-solving iceberg. The broader aspect of operational problems includes the amorphous complexity of the real world. This requires problem formulation, evolving goals and objectives, setting boundaries for the work, designing attractive alternatives for study, screening them, considering unquantifiable (and quantifiable) aspects, and evaluating the resulting outcomes. Perhaps, most importantly, it requires a focus on the problem that is unhampered by preconceived notions of what the solution should be.

Potential OR/MS applications include greater use of techniques such as network flows, for example, system dynamics; stochastic programming of combined fire and human dynamics; reliability and maintainability of fire safety systems; and simulation modeling and analysis of complex interactions of variables including rare events. Of most promise is the use of risk analysis to model the relative value of input from fire physics and statistical analyses of fire losses to modify the

experienced judgment upon which today’s fire safety codes and standards are mostly based.

Often, the issue of fire safety appears too big and too complex for us to comprehend in its entirety. Our solution is to attack bits and pieces of the problem through laboratory research and standards writing. We do not often try to look at the larger picture because that perspective is too difficult. Many tools of OR/MS are designed to deal with large complex problems. A broader perspective may reveal more efficient approaches to fire safety. The late ORSA President Hugh Miser was wont to quote Schön [32] in regard to seemingly intractable problems such as fire safety:

In the varied topography of professional practice, there is a high, hard ground overlooking a swamp. On the high ground, manageable problems lend themselves to solution through the application of research-based theory and technique. In the swampy lowland; messy, confusing problems defy technical solution. The irony of this situation is that the problems of the high ground tend to be relatively unimportant to individuals or society at large, while in the swamp lay the problems of greatest human concern.

To date, there has not been much concerted effort to apply OR/MS to fire safety. In particular, there has been noticeably little OR/MS endeavor on structural fires, where lives are lost, property is destroyed, missions are aborted, and great damage is done to our environment and our cultural heritage.

OPERATIONS RESEARCH APPLICATIONS IN TRUCKLOAD FREIGHT TRANSPORTATION NETWORKS

TED L. GIFFORD
Schneider National, Inc.,
Green Bay, Wisconsin

This article describes a set of decision support systems based on operations research (OR) methodologies that arise in the planning, management, and operations of a large truckload transportation company. These tools support policy development activities and business processes that range across the time horizon from longer term planning cycles to real-time driver dispatching and load management decisions. This discussion will highlight problems and solution models that appear to be either unique to truckload freight transportation or of particular interest in this area.

We draw examples from Schneider National Inc., one of the nation's largest transportation and logistics companies. Although the company's activities are much broader than *truckload* freight, encompassing intermodal operations, supply chain management and engineering, freight management and forwarding, and third-party brokerage, we restrict our examples to the full-truckload segment of the operations. In 2008, this group operated a fleet of 14,000 tractors and 48,000 trailers with a workforce of 15,500 drivers. This freight transportation network spans the contiguous United States and many provinces of Canada. A significant amount of freight also originates or terminates in Mexico and is transferred to/from Mexican carriers at border stations. The freight volume for the year approached two million loads and the total distance traveled was well over 1.5 billion miles. Fleet operations are supported by 15 regional operating centers which include maintenance, refueling, and driver rest facilities. Freight that is carried by these various groups

comes from thousands of distinct customers, although a significant portion originates with a relatively small group of high-volume, consistent, repeat-business customers. Most pricing is determined by long-term agreements, although a significant and growing percentage of pricing is negotiated as part of the tendering process in a daily spot market environment. Almost all freight is tendered within a few days of the required pickup time.

Profitable, efficient management of an enterprise of this size and complexity requires extensive planning processes and tools as well as an array of decision support systems that are based on various models drawn from OR and management science (MS). The review article, "Planning models for freight transportation" [1], provides a good overview of a broad range of models that are common across many transportation modes and describes a commonly-used framework for categorizing these processes and models by time frames. *Strategic planning* encompasses decisions made in a multiyear time frame. These include determining markets, customer demographics, and geographic regions to either increase or decrease focus on, allocating capital funds and resources among various operating groups, deciding whether to open, close, or relocate operating centers based on changes in freight flows, and making adjustments to target levels for driver hiring. *Tactical planning* focuses on those decisions that tend to be durable for one to several quarters. These include specific customers interactions such as contract bid prices and capacity commitments, targeted hiring of drivers from specific domicile regions, schedules for equipment purchase and resale, setting targets and policies for maintenance of trailer pools. *Operational planning* occurs in a time window ranging from a day to one or two weeks. Work in this area is centered on decisions that drive the efficiency and profitability of daily network operations. The most important of these fall into two areas; freight selection—acceptance, targeted solicitation, appointment schedul-

ing; and asset repositioning—empty moves of tractors and trailers to adjust resources to respond to anticipated supply–demand imbalances. We use the term *execution* to denote the daily activity of matching drivers/tractors and trailers to specific loads, monitoring freight in transit, adjusting to changes brought on by such things as weather conditions, accidents, driver emergencies, and customer requests, and managing additional requirements for equipment repositioning and appointment rescheduling.

CONTRAST WITH OTHER TRANSPORTATION MODES

There are some key differences between *truckload* transportation network operations as described here and most other freight transportation *modes*. These other modes include air, railroad, ocean, as well as less-than truckload (LTL) and parcel trucking. The notable distinction between truckload transportation and these other freight transport modes is that the *tactical planning* phase in these modes normally includes the *explicit* determination of routes and schedules for the specific *vehicles* (planes, trains, boats) which constitute the freight transportation network. These routes and schedules are set in advance of knowledge of the realized freight flows and remain relatively static across a predefined horizon. A brief description of air networks (both freight and passenger are similar) will serve to illustrate the general approach for these networks. Forecasts are generated to estimate expected demand over a horizon that typically ranges from three to six months, and also account for expected revenue, costs, and resulting profitability. Using these forecasts as problem parameters, the network design problem of determining routes, route capacities, and schedules is addressed directly, often as a network flow problem.

After setting the structure and capacity of the network, the *operational* problem that remains is to maximize utilization and profitability in response to actualized demand as it arrives. Schedules are published months in advance so that the number of available seats for each route and time slot is fixed. Airlines

then apply sophisticated *revenue management* optimization models to segment customers by buying behavior and adjust prices as a function of booking patterns (accumulating demand), remaining capacity, and time left to departure. These techniques are now notably visible to the general public as on-line airline ticket booking allows customers to see prices change in a matter of minutes. LTL and small package shipping companies also maintain static network routes and schedules, but respond to demand variability by adjusting the number of short trailers that are pulled by a single tractor. Similarly, railroads can vary the number of freight cars and locomotives on scheduled trains to account for actualized freight.

This *two-stage* methodology of *tactically* determining network routing and scheduling and then *operationally* filling out its capacity does not apply for a large *truckload freight* common-carrier. This is driven by the fact that freight is generated by a diverse set of customers, who typically provide short lead times for specific freight movements with service conditions that require shortest-path point-to-point transit. The tractor and sometimes the trailer are now available for redeployment at a time and location that could not be anticipated in advance of *operational planning* and *execution* activity.

MODELING A TRUCKLOAD TRANSPORTATION NETWORK

From a planning and execution management perspective, we should also make clear what we mean by *the network* and how, using OR/MS terminology, we define the *nodes* of our network. As there are well in excess of 250,000 actual *point-to-point* origin and destination locations visited by the tractor fleet in a year, any model that incorporated these directly would clearly be intractable. As such, we subdivide the country into approximately 500 nonoverlapping regions which then become the *operative* locations for modeling and analysis. Postal ZIP3 zones are commonly used as a basis to construct these. Corresponding distances and transit durations are generated by accessing commercial

software packages that provide distance calculations based on detailed information of road and highway networks.

As noted above, truckload freight networks generally exhibit an inherent randomness as the next destination for an asset may not be determined until a short time before the scheduled departure as several or perhaps many different new shipment opportunities may be available for an asset (including moving empty to a better location) when it becomes available at a new place and time. A fundamental concept for analysis of these dynamic, random networks is quantifying the opportunity value of a resource asset at a particular location in the network at the point in time when it becomes available there. As a quantity, this is usually viewed as an estimate of the profit, which can be generated over a specified finite time horizon by the asset looking forward. The quantity is commonly referred to as the *network value* of the asset and is specified by a network location and point (or interval) in time. It may, additionally, be parameterized by the number of similar resources that may arrive concurrently and by attribute values that characterize subclasses of assets. Several of the models and methods described below include as a critical component, the calculation of *network value*.

STRATEGIC PLANNING

Strategic planning problems faced by a large truckload transportation company are generally similar to those encountered in the other freight transportation mentioned above. These include the following:

1. locating and sizing Operating Centers, which provide facilities for equipment maintenance, refueling, and driver services;
2. developing equipment acquisition and disposal schedule and policies. This encompasses determining quantities and types of tractors, trailers, and containers. Decisions on when to retire assets must be based on analysis of maintenance costs, regulatory compliance, and prevailing resale or salvage values;
3. implementing driving hiring and training policies to include setting targets for workforce size, training programs, and determining the desired demographic mix of drivers;
4. negotiating long-term contracts for fuel prices and fuel hedging strategies;
5. entering into bid agreements with customers for longer term pricing and capacity commitments.

Of the above, only the third appears to present a unique challenge to long-haul trucking, which we describe in the following section. For the other areas, Crainic and Laporte [1] provide an introduction to strategic planning problems that apply across a range of transportation modes and a broad range of references.

TACTICAL PLANNING

Among the planning problems and operational policy decisions, there are several that appear to be unique to large-scale truckload transportation networks. In particular, the *truck driver* is a critical resource and subject to unique constraints and cost factors. The industry average for driver turnover is approximately 100% annually, that is to say, in order to maintain a workforce of 10,000 truck drivers, an organization will need to hire approximately 10,000 new drivers each year. The cost of recruiting and training replacement driver costs can cost up to \$7,000 and costs related to both efficiency and safety are considerably higher for drivers with less experience. Consequently, improved driver retention is both a key competitive differentiator and contributor to low-cost operations. The primary factor affecting retention is the ability to get drivers back to their domicile (home location) on a consistent and relatively frequent basis. Because of the random nature of large truckload networks, operational efficiency requires drivers to typically remain away from home for up to several weeks. Figure 1 depicts a sample one-month tour for a long-haul driver with two layovers (one occurring at home and the other on the road).

Another dimension of driver cost directly relates to the hours of service (HOS) rules

Figure 1. Typical month-on-the-road for a long-haul driver.

mandated by the Department of Transportation, which governs driver work schedules (see below for further discussion of these rules). The ability to model these complex rules in the context of large random transportation networks can improve operating decision policy choices as well as provide an effective tool to evaluate the impact of proposed changes in these rules.

A successful approach to these problems has been developed using the framework of approximate dynamic programming (ADP) [see, in particular, Powell 2], and close collaboration between industry subject-matter experts and academic researchers. This project as well as a thorough overview of the technology is reported in Ref. 3. Building on an extensive body of research conducted at CASTLE Lab, Princeton University, a tactical planning simulator (TPS) was developed to simulate real-time dispatch operations for a large truckload freight transportation fleet. The TPS has proved to be particularly well suited to investigate issues wherein the detail-level attributes of specific resources and their interaction with decision rules and

operating policies have a dominant impact on system performance.

The TPS provides a realistic simulation of 6000 drivers moving across a nationwide network transporting over a three-week time period during which approximately 50,000 shipments are simulated. Figure 2 below depicts the general framework for the system. The nodes in a vertical plane represent one of the planning regions for a 6-h time interval and a row of nodes represents successive time steps for a given region across a three-week simulation cycle. The figure is simplified representation, as the actual TPS simulator explicitly models each driver and load, with arrivals and departures captured in continuous-time. At each node, a set of shipments are available corresponding to loads outbound from the region with pickup appointment times that fall in the corresponding time interval. These shipments can either be randomly generated to simulate actual freight flows as derived from historical data or may represent forecasts of expected freight. Drivers initially become available either at the beginning time step

Figure 2. Planning simulator network flow structure with value functions (from Ref. 2, p. 410).

or at a point corresponding to a *simulated* entry into service. During an initial *forward pass*, a driver-to-load assignment problem is solved at each node *assigned* drivers next become available at the node corresponding to the destination and arrival time of their *assigned* load. The *objective function* for these sequential assignment problems is comprised of four types of costs or contributions:

1. direct *hard* costs associated with the particular driver-load match, most notably the *deadhead* travel distance and time;
2. *soft* costs intended to capture difficult-to-quantify ramifications of the particular assignment, such as the extent to which the load may move a driver back toward his/her domicile;
3. costs intended to steer the model toward decisions that are representative of the *real-world* solution accounting for qualitative trade-offs and adherence to policy guidelines not captured in a traditional mathematical model;
4. future value that represents the *network value* described above: it is an estimate of the marginal *future* value that the driver will contribute to the overall solution at the destination location (and time) if the assignment is selected.

Cost types (1) and (2) are described in more detail in the section titled “Execution” below as they are used in the driver-load matching algorithm used to support the real-time

dispatch process. Type (3) cost factors are derived by establishing a set of *business operating metrics*, which form *patterns* to which the solution will be *encouraged* to adhere. These *pattern metrics* specify the expected percentage of freight with certain attributes that should be transported by drivers with various characteristics, as well as the distribution of freight mix that should be moved in cases where extra freight is available. For further discussion of this technique and its application, see Refs 3 and 4. Cost type (4) lies at the core of the ADP approach and is computed empirically via dynamic programming recursion. Each iteration of the simulation consists of a *forward pass* during which the driver-load matching problems are solved by simulating dispatch decisions forward through time, followed by a backward pass in which the *realized* marginal values of drivers of each attribute class (e.g., domicile, type, remaining driver hours, and number of days to scheduled time-off) are updated with new information from the most recent forward pass. Figure 2 is a representation of the TPS network structure showing the value functions (cost type 4) that are updated with each successive pass.

To address the time-at-home (TAH) aspect of the driver retention, the TPS was configured to estimate the relative changes in operating profit as a function of driver populations for the various domicile regions. The home location of long-haul truck drivers has a significant impact on network operating efficiency, since the trip from home to the first load start and to home from

the last load end results in additional cost due to unbillable miles and unproductive time. As profitable freight flows are largely determined by geographic production, distribution, and consumption patterns, targeted driver hiring in specific regions is the most effective lever to address this issue. It is also the case that driver hiring costs and salaries exhibit geographic variation, often producing the highest wages in regions where Schneider originates the most loads. Using TPS simulations, it has been possible to quantify the marginal contribution differentials between regions, which may vary by up to \$1000 per month per driver. This analysis is used to determine more efficient advertising, incentive, and regional salary differential policies. Benefits have been conservatively estimated at \$5 M annually. A closely related analysis, which led to adjustments in proposed driver self-scheduling policies, is estimated to achieve a net annual benefit of \$25 M. For a comparison with other techniques, see Ref. 5. This work studies the driver domicile problem in the context of an LTL shipper and provides an interesting contrast to our truckload discussion as both the constraining factors and the solution approach are very different.

The TPS has also been effective in evaluating the economic impact of HOS rules changes and providing insight into strategies to mitigate productivity declines. Several years ago, the US Department of Transportation has introduced significant changes to driver work schedule constraints. The new rules increase the maximum driving time from 10 to 11 h but require all driving to occur within a single 14-h interval. Additionally, the new rules allow the 60 h/week limit to be refreshed with a continuous 34-h break. Using TPS simulations, it was possible to both quantify these impacts and evaluate the mitigating effect of adjustments to customer constraints such as pickup/delivery time-window and yard management policies. With this information, it was possible to appropriately negotiate adjustments in customer billing rates and freight tendering/handling procedures, resulting in a near complete offset of these potential productive impacts. The simulator was also used to evaluate the efficacy of the

34-h *restart rule* and to develop guidelines for practical implementation.

OPERATIONAL PLANNING

Operational planning activities normally occur within the week preceding freight movements that these activities will influence. The primary goal is to make decisions that maximize the efficiency and profitability of daily network operations. There are two key metrics that measure this success, *billed ratio* and *load profitability*. *Billed ratio* is the ratio of revenue-generating miles to total miles driven and is improved by reducing empty miles required to reposition equipment to balance supply and demand. *Load profitability* measures the profit attributable to a shipment and is a function of revenue, direct and allocated costs, and the *network impact* of the resource repositioning resulting from the shipment execution. To influence these metrics, OR-derived decision support tools for both *freight selection* and *network management* have been developed to help planners directly influence *profitability*, *demand*, and *supply* within limitations determined by market conditions, customer commitments, and fleet capacity. These tools focus on two business process areas, freight selection and asset repositioning.

With 9500 loads per day tendered by customers, a majority of which are communicated and processed electronically, automated systems are required. The *Freight selection* process is supported by automated tools for *load acceptance*, *spot pricing*, and *solicitation*. Although a majority of loads fall under long-term contract pricing agreements, a significant number may be *spot priced*, particularly during times of greater competitive market pressure. Additionally, for select large customers, the carrier may have a contract commitment to move a minimum number of loads from an outbound region on any given day.

The *load acceptance tool* is a real-time decision support system that evaluates customer loads as they are tendered to determine whether or not it should be accepted for movement and additionally evaluates feasible options for both, the capacity type and

Figure 3. Time-space flow network for LP formulation.

possible pickup and delivery options. The system provides the estimated profit that will be generated by the load for each of the feasible parameter combinations, which may be available for execution of the load movement. Since the contemplated load movement will result in a redistribution of network capability, the impact of this asset reposition must be taken into account. The equation used to determine this value takes the form

$$P = R - C + V_{d,t} - V_{o,s}, \quad (1)$$

where P is the profit or value to be realized; R is the revenue associated with the shipment, C is the total direct and allocated cost associated with the shipment, and $V_{d,t}$ and $V_{o,s}$ represent the opportunity cost of the asset at the destination at time t and the origin at time s . These are specific examples of the *network value* described above. Their importance is reflected in the fact that freight transportation networks can often exhibit significant demand imbalances. Two oft-cited examples of these are (i) the flow of Asia-originating consumer products from West Coast ports to population centers in the Midwest and East that cannot be completely offset by the flow of freight westward and (ii) the lack of freight moving north out of Florida other than seasonal fruit products to provide a balance to consumer products moving to the large populations in south Florida. C is defined to include all costs

that can either be attributed directly to the shipment or can be allocated independently of how flows in the network are realized. Consequently, the calculation of values for $V_{o,s}$ and $V_{d,t}$ represents the main challenge. $V_{d,t}$ represents the anticipated profit opportunity for the asset (tractor/trailer) when it completes the current shipment at location d and becomes available for a subsequent shipment at time t . Similarly $V_{o,s}$ represents the value of alternative profit opportunities, which were otherwise available to the asset at location o and time s .

There are several methods available to estimate the values $V_{d,t}$. The classical approach is to leverage linear programming (LP) duality, using a network flow formulation with nodes corresponding to distinct geographic region/time interval combinations. Figure 3 depicts the directed graph for such a network flow formulation. A common approach is to implement a three-week planning horizon using short time intervals in the first week and longer ones in the second and third weeks; for example, 6-, 12-, and 24-h intervals for weeks 1, 2, and 3, respectively. This choice is based on the fact that approximately 90% of all freight is tendered within the week prior to pickup and at the end of a three-week look-ahead, it is reasonable to assume a common *salvage* value for assets. Consequently, a representative example for a large national freight network with up to

500 distinct planning regions and 50 time intervals would have 25,000 nodes. The average number of outbound arcs per node is about 50, giving a total of 1,250,000 arcs.

There are three type of arcs in the network; (i) *loaded arcs* represent freight movement, an origin/pickup time-window to a destination/delivery time-window corresponding to the estimate transit time to travel from the origin to the destination, (ii) *empty arcs* represent repositioning of trucks from one location to another with the appropriate time displacement, and (iii) *hold arcs* represent the decision to hold a truck idle until the next time interval in anticipation of a better opportunity. These arc flows are constrained by lower bounds representing shipments already accepted together with additional known commitments and by upper bounds representing forecasts for the number of additional loads that are expected to become available. For arcs in later time periods, less actual information is known and forecasts are more uncertain. There will often be multiple parallel *loaded arcs* representing shipment opportunities at different profit levels corresponding to varying customer contracts and spot market price estimates.

Additionally, node balance constraints insure that the number of trucks entering a node generally equals the number departing. Nodes in the first time period are source nodes corresponding to the starting (i.e., current) distribution of trucks and the *sink* node at the right receives inbound flows representing asset “salvage” values at the problem horizon. Intermediate nodes, particularly those in early time intervals, may have positive or negative balance corresponding to known plans for trucks entering or leaving service.

Although the *primal solution* to this network flow problem gives an *optimal* set of flows for the problem as described, it is of no direct interest, as the realization depends both on the freight selected and the *execution* level driver–load matching described below, the *dual values* associated with various model constraints can provide reasonable estimates of opportunity cost.

While the dual values associated with lower-bound (upper-bound) arc constraints represent the potential value of relaxing a commitment to move freight at a specified profit level [of the value of additional (i.e., above the forecast) freight], our interest is in the node balance constraint duals. If the value is positive, it provides an estimate of the value of obtaining an additional truck in the corresponding region and time slot, and, if negative, the savings associated with having on fewer. This approach has proved reasonably successful as a mechanism for generating the values $V_{d,t}$, used by the *load acceptance tool* described above. In current practice, the model is refreshed with updated information on known and forecasted freight and driver/truck available and rerun approximately every 15 min.

The *spot pricing tool* provides guidance for price negotiation to customer service representatives (CSRs) receiving freight tenders in the spot market. In this environment, customers are often shopping for the lowest price that meets their service requirements. This tool is comprised of two components. A binary logit choice model is used to derive the probability that the customer will accept a specified offered price. Some of the factors found to be significant for this model include customer incumbency, day of week, time of day, guideline or corresponding contract prices, and whether the offer is for multiple loads. The price associated with a target acceptance rate is then applied in Equation (1), to estimate the resultant profit. Depending on current capacity availability and general market activity, management can then adjust thresholds for profit and acceptance to balance fleet utilization with profit objectives.

Network management encompasses a planning process that attempts to minimize supply/demand imbalances across the broad network over a moving several-day time horizon. Using a hierarchical approach, high-level area planners have responsibility for freight flows in and out of large multi-state regions of the country; for example, the northeast, the upper Midwest, and so on. At the next level, region planners review current balance forecasts within

specific regions and time intervals. These are segmented to be small enough and narrow so that a driver destined to arrive in one of these region-time slots would be a reasonable choice for assignment to a shipment available for pickup in the same. Typically, such a region will have a diameter ranging from 25 to 100 miles. There are several hundred regions with sufficient volume to support active planning. Corresponding time slots normally range between 4 and 8 h depending on freight volume. Figure 4 illustrates this balance situation and depicts the contributing factors. On the supply side, trucks become available as (i) drivers complete delivery of inbound shipments and become available for a new assignment, (ii) drivers come off their *weekend* or TA, (iii) or transfer off of an in-transit or *relayed* load. On demand side, trucks are (i) assigned to outbound loads, (ii) go out of service as drivers start a TA interval, or (iii) assigned to take over *relayed* loads. During this stage, planners are not directly concerned with individual assignments, which we describe in the following section, but rather with trying to ensure that the number of available trucks will match the number of shipments that have been committed for movement.

In order to achieve this *node balance* within the network, there are several different *levers*, one can pull.

1. The *load acceptance tool* naturally encourages acceptance decisions that positively affect network balance through the influence of the V terms

in Equation (1), as shipments that contribute to balance at an origin node will have relatively smaller values for $V_{o,s}$ indicating less incentive to *conserve* capacity at O and those with relatively larger values for $V_{d,t}$ will encourage the movement of freight into a node with capacity at a premium.

2. Similarly, the *spot pricing tool* will tend to recommend softer pricing along lanes and time frames that will reduce imbalances. This occurs through the profit estimate provided through Equation (1) as well as explicit reduction of profit target.
3. A proactive *solicitation* program uses a decision support tool to match profitable lanes with customer tendering patterns and then directs CSRs to reach out to specific customers for additional freight.
4. In many cases, customer service constraints provide wide windows for either pickup or delivery times. In regions where imbalances appear short-lived rather than chronic, adjusting appointments earlier or later can help reduce imbalances.
5. The freight networks for different capacity types—team and solo drivers, intermodal, brokerage to third-party carriers—are managed somewhat independently. In some situations, different capacity types may exhibit *complementary* imbalances, allowing the conversion of compatible freight from one type to another to

Figure 4. Network balance at a node with contributing flows.

positively influence balance in both networks.

6. The least desirable option is to move drivers from a region of excess capacity to one nearby with available freight. This is usually least desirable as near-full cost is incurred with no revenue generated. Repositioning schedules are established in this planning phase and individual driver moves are specified in the execution activities described below. When conditions require extensive multiregion repositioning, a straightforward min-cost network flow model is sometimes employed to determine the least cost region-to-region transfers to achieve the desired supply levels.

DISPATCH AND EXECUTION

Execution encompasses the decisions related to direct control of specific assets on a day-to-day basis. The related tasks are referred to as the *dispatch process* and include (i) assigning drivers/tractors to specific shipments, (ii) relaying in-transit loads from one driver to another to adjust to unexpected situations, and (iii) determining specific drivers to either reposition or hold.

As described in the previous section, one of the primary short-term planning goals is to assure that within a relatively small planning region and time slot, the number of tractors available for deployment is sufficient to cover the full trailer-loads of freight that have been accepted and scheduled for delivery. The *dispatcher's* task is to determine which specific drivers to assign to which loads. Depending on timing and other circumstances, the dispatcher may sometimes have either a single specific driver in mind, for whom a next load needs to be found or a specific load that needs to be covered. However, more general (and computationally interesting) is simultaneously finding a set of good assignments for a group of drivers who are converging on a *node* in the space-time network we have described above. The applicability of a classic

operations research model to this problem was first recognized and implemented in the 1970s. Powell [6] provides an excellent overview and perspective on this problem and its implementation at several truckload motor carriers. He also addresses important additional considerations including trailers and demand forecasting. A related article, by Powell *et al.* [7] provides an interesting account of human-system interaction in the application of this technology, addressing issues such as model trust and dispatcher compliance with system-generated recommendation.

This difficulty with effective implementation of this approach lies not with model or solution complexity, but in defining effective *filtering* and *costing* rules to generate the model arcs. The *filtering* step consists of determining whether a driver is a feasible choice for a given load. Some of these, notably whether a driver is qualified to haul a given load; for example, hazard materials or appropriate border crossing documentation, are straightforward to apply. For others, it may be unclear whether the best strategy is to implement a *hard* constraint or to allow the arc with an addition *penalty* cost component to allow a constraint to be violated when few or no other opportunities exist for the driver or load. The components that comprise the cost value for an arc corresponding to a specific driver-load match can include the following:

1. *NAL*. Distance from driver's next available location (NAL), usually either the prior destination or park location, if entering service, to the load pickup location multiplied by a *deadhead* travel cost factor;
2. *NAT*. Time delay from the driver's next available time (NAT) to the pickup time-window for the new load, multiplied by a *waste time* factor, if appropriate. (Typically, a filtering rule incorporating the driver's NAT and NAL is also applied to determine if the driver can meet the customer time window.)
3. *DOT Hours to Run*. Based on DOT driver time rules described earlier, an

available driver may either require a break before beginning the new load or will have a certain number of hours left to run. A *productivity fit* cost factor is calculated to estimate how well this remaining time meshes with the appointment time windows or service constraints of the load.

4. *Trailing Equipment Compatibility.* Upon completing a load, a driver may or may not have an empty trailer. Similarly, the next load may or may not require the driver to bring an empty trailer to the pickup location. If the driver and the new location *match* in this sense, then the driver may proceed directly to the pickup. If not, costs are applied to account for the time and distance required for the driver to drop, acquire, or exchange a trailer before proceeding to the pickup.
5. *Driver Time-At-Home.* In a previous section, we discussed ways to address driver time-off in the tactical time frame. In the dispatch process, we need to make specific assignments that will get the driver home as promised while minimizing costly empty drive time. To do this, a bonus (penalty) cost adjustment is made to the assignment arc to reflect how well (poorly) the load will *set a driver up* to meet his/her off time schedule. A common approach has been to implement a *time-to-distance* offset that conceptually defines concentric geographic rings around the driver domicile and rewards loads that move a driver to inner rings as his/her TAH date approaches. An alternative approach is currently being evaluated with the TPS which develops simulation-derived transition probabilities.

While the driver-load assignment process addresses normal “sunny day” operations, it is often the case that shipments must be handed off or relayed to another driver in transit. This may be necessary due to equipment breakdowns, unexpected driver time-off requirements, or time recovery for loads running late. Optimization tools have

been developed that extend the logic of the driver-load assignment model to scan network activity to, evaluate and rank *relay opportunities* considering hard and soft costs.

Although network planners work to setup a balance of driver and loads in each region on a daily basis, specific “stay or go” decisions often need to be made in real time when a driver is ready for a next assignment and none are available within the normal time or distance tolerance. Should the driver “stay” and remain idle at his/her current location until freight becomes available or should the driver run empty (incurring a significant deadhead cost) to another region where freight may be available? Using a decision support tool that relies on a very short-term demand forecast and accounts for costs associated with either option, the dispatcher is provided guidance on when and where to shift drivers.

CONCLUSION

This article has highlighted a subset of the planning and operations problem encountered in large-scale truckload networks and a selection of OR/MS based decision support tools that have been implemented to help solve them. While some of the models utilize advanced techniques and a level of sophistication that supports coverage in current literature, in every case, the initial and ongoing justification for investment has been borne out by verifiable economic benefit. In order to maintain this objective, improvements are ongoing. In particular, the TPS is being enhanced to address a wider range of issues, including the capability to evaluate and quantify specific customer requests related to service constraint changes and freight characteristics. Variations to *network value* calculations described in the section titled “Tactical Planning” are also under consideration. These include (i) the use of TPS value functions, (ii) techniques to lessen the sensitivity to forecast error by employing robust techniques along the lines of those described in Ref. 8 or unconstraining methods

as described in Ref. 9, and (iii) the application of average rather marginal costing for certain network value applications.

OPERATIONS RESEARCH APPROACHES TO ASSET MANAGEMENT IN FREIGHT RAIL

MICHAEL F. GORMAN
STEVEN HARROD
Department of MIS, Operations
Management, and Decision
Sciences, University of Dayton,
Dayton, Ohio

INTRODUCTION

The objective of this article is to provide an overview of the theory and practice of operations research (OR) in asset management in the freight rail industry. In an accompanying article (see *Operations Research for Freight Train Routing and Scheduling*), we describe how freight rail service is designed using OR. That is, this article addresses, primarily, the provision of assets, and the companion article addresses the strategic and tactical deployment of those assets, through scheduling. Here, we describe the five primary assets required to provide freight rail service and how OR contributes to improved decision making surrounding each asset.

Trains require five different resources to run. The “physical plant” consists of the fixed infrastructure or network assets such as rail lines and rail yards or terminals (for intermodal). The “mobile resources” are crew, locomotives, and railcars. The second section describes the OR techniques that apply to mobile assets, the third section discusses OR modeling of lines and yards, and the fourth section concludes the article.

In each section, we describe OR modeling approaches as they are applied to strategic, tactical, and operational decision horizons. For example, locomotive fleet modeling might address strategic issues such as long-term fleet sizing over a multiple-year horizon, tactical modeling might focus on meeting train

needs on repeating weekly train scheduling, and operational modeling might focus on locomotive repositioning given a regional surplus or deficit. Similar decision horizons have been applied in the OR modeling literature surrounding the other rail topics.

MOBILE ASSETS: LOCOMOTIVE, CARS, AND CREW

The mobile assets that make up a train are cars, crews, and locomotives. Only the railcar follows a customer shipment from its origin to its destination. A train may carry a shipment for some portion of its route, which is not usually the same as the train’s origin and destination; a shipment often moves on many trains. A set of locomotives, called a *consist*, are typically assigned from the origination to the termination of a train. Crews are assigned to a small (often four to eight hour) portion of a train route called a *crew district*; trains have a crew change at each change in crew district. Because each asset is subject to entirely different management rules, different OR approaches govern each.

Railcars

Before service to a customer can be provided, an empty railcar is delivered to the customer origin. In the case of intermodal, an empty container or trailer must often be delivered. OR modeling is applied to deciding which empty should be assigned to which customer order. See Dejax and Crainic [1] for a survey on this subject.

Some work has been done on the strategic railcar fleet sizing problem, which establishes the appropriate number of cars to support forecasted traffic in steady state [2–6]. Considerations include on-time service and back-orders; stochastic supply; demand and travel times; and fleet utilization.

The tactical empty railcar assignment problem is typically expressed as a transportation problem or conservation of flow problem.

The first challenge in such problems is to sort through the plethora of car attributes and car orders to assure a quality solution.

Car attributes may be categorized as static or dynamic. Static attributes include car type (box car, gondola, flat, etc.), length, and capacity. Dynamic attributes include date and location of next availability. A set of customer preferences on car orders specifies desired and near-substitute car types and the desired delivery location, date, and allowable delivery window. Between subsets of cars and car orders over the horizon that spans a few weeks, there is a set of allowable assignments based on these attributes. The cost of any allowable assignment includes the time, distance, and yard handling cost of empty movement to the railroad, as well as qualitative factors such as car-to-order mismatch, early and late delivery, and unmet order cost. The total costs of assignments are minimized through optimal car-to-order assignments.

Because the OR modeling for this problem is relatively straightforward and quick to solve, standard LP solution methods have been applied. As a result, real-time tactical empty car distribution models have been among the most effective and widespread in the rail industry. Gorman *et al.* [7,8] describe successful applications and BNSF and CSX railroads, and Narisetty *et al.* [9] describe an implemented system at Union Pacific. Sherali and Suharko [10] describe an effort to distribute automotive railcars amongst the major North American Railroads, and Gorman [11] describes real-time container distribution in intermodal. Key challenges in implemented decision support systems include constantly evolving car supply and car order information coupled with sequential assignment practices, as well as stochastic delivery times.

Extensions to the commonly implemented approach include the inclusion of stochastic car supply, customer car orders, and delivery times for empties [12]. Each of these applications focuses on the near-term decisions of assigning empty railcars to current orders. The models could be critiqued as myopic; car assignments made today affect future supply conditions after a shipment is completed and the car becomes empty again

(often a week or two in the future). Powell and Topaloglu [13] and Topaloglu and Powell [14] propose an approximate dynamic programming approach to capture the effect of future network conditions when making car assignment decisions. Similarly, Powell and Carvalho [15] propose a logistics queueing network approach for tactical flat car and container management in intermodal. Along a different line, Joborn *et al.* [16] describe economies of scale in equipment distribution when empty cars do not travel in predetermined blocks. They propose a tabu search approach to this network mixed integer problem with side constraints.

Train Crews

Train crews work in teams to move a train across its route. The train goes through numerous crew districts or geographic corridors; in each crew district, the train is manned by a single crew (usually two people: a conductor and an engineer) that is qualified to operate a train in that district's unique topography. The crew district represents one job for a crew, and the job is usually between 4 and 8 h. At the transition point between two districts known as the *crew change point*, one crew exits and another enters the train, and the train continues on its way into the next district. Each crew has a "home," terminal, works a train to an "away" terminal, then subject to on duty and rest time restrictions, works another train in the opposite direction back to its home. In some cases, districts are "double-ended", meaning that there are two different pools of crews, each with a home at each end of the district.

The difficulty of managing train crews comes from managing the costs against the constraints of the problem. In most cases, crews must receive some minimal rest between trips; thus, an inventory of rested (and resting) crews must be maintained at both ends of the district because it is of paramount importance to avoid crew-related train delay. On the other hand, at the away terminal, if the time between trips exceeds some contractually agreed upon number of hours (usually 16), the crew receives detention pay. By labor agreement, particular to the North American freight rail

industry, crews must be called in *first in, first out* (FIFO) order. In many cases and over many time intervals, the number of trains in each direction may not be balanced; thus, either detention pay mounts, or the crew can be “deadheaded,” or moved back home (or away) at some cost via taxi or train without providing productive service.

Extensive work has taken place with airline and passenger European rail crew scheduling (see for examples, Barnhart *et al.* [17] for airline, and Caprara *et al.* [18], Kroon *et al.* [19], and Ernst *et al.* [20] for European passenger rail), but these methods do not apply directly to the freight rail crew management problem described above because of rules such as FIFO described above.

Only two articles [21,22] have been written specific to North American freight rail. Both models are tactical in nature, that is, they are solved with an initial crew starting position. The objective is to minimize the sum of crew wages, deadhead costs, and crew detention. In both cases, the solution is subject to the constraints: all scheduled trains are covered by exactly one crew with no delay and rest rules are obeyed. Gorman and Sarrafzadeh [21] use dynamic programming to solve the singled-ended crew district problem to optimality in seconds, but this method does not handle more complex two-ended districts.

Vaidyanathan *et al.* [22] describe the two-ended crew district problem decision process and model it as an integer multicommodity flow problem with side constraints on a time-space network. The approach of Vaidyanathan *et al.* requires explicit modeling of crew flow balance and handling of the FIFO constraint, which is inherent in the dynamic programming approach. Vaidyanathan *et al.* use LP relaxation and iterative branch and bound to solve the much larger and complex formulation. The authors report near optimum results in seconds or minutes, depending on the problem.

Of all the moving assets, crews are most subject to deviations in the train schedule because crew inventory and dwell time must be managed most closely. Train annulments, second sections, and delays in existing trains can directly affect the quality of the plan in a crew district, either increasing detention or

deadhead cost, or causing train-related crew delay. The methods developed to this point focus on the deterministic case, but the risk associated with stochastic train schedules is of great importance to decision makers and largely uncovered in the current research. See Walker *et al.* [23] for an example of crew recovery planning.

Locomotives

Locomotives are usually assigned to trains in “consists”—groups of locomotives with similar operating characteristics measured in horse power and number of axles. The minimum required consist for a train depends on the train size (in tons). The consist must have a sufficient number of required axles to provide sufficient tractive effort to move across the route’s topography, and the required horse power to move the train at speeds that meet its schedule, often described as the required HPT (horse power per ton) ratio. The inventory of locomotives must be managed at origination yards to assure that locomotive requirements and preferences are met without delay.

Similar to railcars at load destination and crews at crew change points, locomotive supply at train origin is driven by their previous use on a train. In this case, supply is usually created at the train termination. There is a handling cost to adding or subtracting locomotives from a consist; so where possible, consist “busting” is avoided by connecting the entire consist of a terminating train to an originating one.

Often a freight imbalance drives the need for locomotive repositioning to or from a yard. Locomotive repositioning occurs either in a scheduled train, known as *deadheading*, or independently, known as *light travel*.

As described in a survey article by Cordeau *et al.* [24], little published work has been conducted on strategic models on locomotive fleet sizing (one recent example is Godwin *et al.* [25]). The focus has been more on steady-state locomotive planning to support a weekly schedule, or tactical locomotive scheduling given a starting inventories at yards in the rail network. Early work focused on single-locomotive scheduling [26]. More recently, the more useful locomotive consist

problem has been considered [27,28], as well as joint distribution of locomotives and railcars [29].

The locomotive scheduling problem is formulated as a multicommodity flow mixed integer problem with side constraints. The decision at each yard is which locomotives to assign to which trains, recognizing that these assignments affect downstream locomotive supply (usually one to a few days in the future). The objective in the problem can vary, but often includes minimization of train overpowering (and underpowering, if allowed); locomotive idle time; deadheading and light travel; and consist busting and consist inconsistency costs. The constraints are to supply sufficient locomotives to all trains such that they can depart on time and run on schedule. Additionally, there are minimum and maximum locomotives on each train, as well as minimum times for locomotive connections between trains that must be obeyed.

Because of the locomotive scheduling problem size for realistic examples, heuristics have been used to provide near-optimal solutions. Early single-locomotive models used Benders decomposition and Lagrangian relaxation. Ziarati *et al.* [30] use Dantzig–Wolfe decomposition and shortest path algorithms applied to the multiple locomotive problem at the Canadian National (CN) railroad. Ahuja *et al.* [27] propose decomposing the problem into two stages and very large-scale neighborhood search to a problem at CSX railroad.

The problem is made more complicated when one considers that individual locomotives within a consist have mandated service requirements, and often must be routed to a shop, ideally while productively providing tonnage hauling in a train consist [31]. Similarly, locomotives have individual refueling histories and fuel efficiency, thus have independent fueling needs. These additional constraints restrict paths locomotives can take, and because of consist mix rules, can affect the flows of other locomotives as well. Locomotive schedules are further complicated by delayed or canceled trains, or yard congestion. The locomotive consist planning and scheduling problem remains

one of the more difficult OR problems in rail asset management.

NETWORK ASSETS: YARD AND LINE PLANNING AND OPERATIONS

The network on the ground, the mainlines, sidings, signals, and classification yards, determine the feasible region of railway operations. Poorly configured sidings or inefficient yards may severely handicap railway transport capabilities regardless of any efforts to mobilize labor or improve locomotives or rolling stock. Further, the network on the ground nearly always has a long functional life span, represents a large financial investment, and requires a lengthy investment return period. Consequently, changes to or extensions of the network are made cautiously and according to well-tested calculations. Pachl [32] provides a general purpose text on railway installations, signaling systems, and operation.

Signals and Communications

While signals and communications are significant factors in the capacity enhancement of dense passenger services, innovations in signals (beyond the established fixed block color light system) are less important to the capacity of heavy rail freight. The primary reasons for this are the acceleration and deceleration characteristics of heavy freight trains. In order to minimize wear and tear, heavy freight trains avoid frequent, heavy braking, and likewise avoid fast acceleration to save fuel. Consequently the signal response times and headways necessary for cost-effective operation are significantly less stringent than those required for safety or shared operation with passenger trains. Dinger *et al.* [33] make an extensive analysis of communications based or positive train control within a heavy freight network and enumerate scenarios where advanced signals and communications will improve capacity, and scenarios where they will reduce capacity.

Line Capacity and Planning

The decisions faced in specifying a railway line generally include the number of parallel

main lines and the size and location of additional short tracks to allow trains to wait and allow each other to pass, called *sidings*, as well as the location of connections between main lines, called *crossovers*. If more than one main line track is specified, there is a choice of whether to limit each track to a single direction of flow or to provide signals and communications for bidirectional flow on both tracks. Sidings may be specified at different lengths, either to support trains of different lengths or according to whether a train will stop and wait in the siding or attempt to continue moving.

The impact of siding placement and its effect on traffic is a frequent topic. An early analytical study by Frank [34] estimates maximum flow for a single track line operating at one speed and demonstrates that under some scenarios of dispatch double sidings supporting two waiting trains allow greater network flow. This observation received no further attention until Harrod [35] demonstrated that some scenarios with mixed speeds also benefit from double sidings. Petersen and Taylor [36] consider the design of a mixed traffic single track line for shared use by slow freight trains and high speed passenger trains, and conclude that a carefully planned and dispatched single track line could perform acceptably compared to a double track line. Higgins *et al.* [37] present a mixed integer programming model with the objective of determining the location of sidings on a single track line to support a given traffic pattern. A Benders decomposition solution scheme is used. Finally, Landex [38] presents single track parametric measures of capacity derived from the UIC (International Union of Railways) standard 406.

Simulation has played a prominent role in line planning. The origins of early train performance calculators and dispatch simulators are documented by Wilson and Hudson [39] and Wilson and Lach [40]. Prokopy and Rubin [41] simulate a wide variety of typical North American operating scenarios and then estimate statistical or parametric functions of capacity from the simulation results. Kraft [42] gives a focused comparison of analytical and simulation models for line planning. Welch and Gussow [43], finalists for the

1985 Franz Edelman Award, describe many innovations in their simulation model, again at Canadian National Railway. They describe improvements to lockup prevention (lockup is when trains are mistakenly dispatched into terminating, infeasible paths) and the representation of double main lines. They found, for their operating pattern, that signal blocks should be shorter and that double tracks should be evenly distributed along a route and at the entrances to yards. Public policy decisions in line planning are considered by Leilich [44]. Krueger [45] presents statistical estimates of capacity calibrated to simulated operations of Canadian National Railway. Lai and Barkan [46] extend this model with an application that automatically enumerates a wide range of line improvements and estimates the resulting network capacity.

Many railway infrastructure projects are now joint or publicly financed projects, introducing an additional element of financial and political risk to the outcome of the planning process. A number of authors give warnings on the interpretation of simulation and design analysis. Wood and Robertson [47] present cautionary lessons drawn from life experiences on the failure to calibrate line design to intended train timetables. Harris and Cordon [48] demonstrate that infrastructure investments may require some utility function of multiple measures to justify their approval. White [49] expresses concern that simulation output may be misinterpreted, particularly if only one performance measure is considered.

Yard Design and Operation

Yards are the heart of railway operations. They direct and measure the flow of traffic throughout the network, and are the most critical factor in accomplishing the transportation function. Indeed, Mierzejewski [50] has extensively documented that only after Allied forces shifted their bombing focus from main lines to yards was the German economy finally disrupted in World War II. Dramatic service failures ensued after the merger of Union Pacific and Southern Pacific due to the failure to properly manage classification in the Houston area in 1997 [51].

Yards occur in a range of sizes, but primarily two forms: the flat yard and the hump

yard. The flat yard is very labor intensive, but may be worked simultaneously by multiple switch crews. The hump yard contains a man-made hill at one end over which whole trains are pushed and released, one car at a time, so that they may roll by gravity into a programmed track. With automation a hump yard requires very little labor. However, a hump yard may only sort one inbound train of cars at time.

Differences in train technology can severely limit the application of hump yards. In particular, some traffic is prohibited in hump yards in North America due to technical limitations, and multicar blocks do not handle well on humps. Wong *et al.* [52] provide a comprehensive engineering and economic guide to the planning and installation of yards. Kraft [53,54] reviews the interplay between North American railway scheduling strategy and classification yard technology from a 100 years ago to the current date.

OR topics in classification have progressed from simulation, to queueing, and to analytical studies. To address the problem of excessive dwell time in yards, Crane *et al.* [55] demonstrate a very early simulation of yard operations. Applied simulation models have since played a vital role in strategic management. Indeed, Troup [56] refers to simulation as “the most advanced tool for studying and analyzing rail yard operations.” Troup provides a detailed and still relevant manual to yard operations.

A few studies derive queueing models of classification yard operations [57–60], but queueing methods have not generally been accepted in practice. Martland [61] expressed concern that prior queueing models required unrealistic presumptions of steady-state processes. Martland describes a method called PMAKE (“probability of making a connection”) and notes its extensive application record in North American operations. Martland calibrates a number of cumulative probability functions for the time to complete a connection as a function of yard dwell time, congestion, car status, and other variables.

Daganzo [62–64] investigates the specific quantity and sequence of switching moves required according to traffic volume and

yard dimensions. Daganzo considers fixed block assignments to yard tracks (“static” blocking), dynamic blocking, methods of handling strings of cars, and a variety of strategies for prioritizing the classification of cars. He *et al.* [65] apply computer-aided dispatching to classification yard scheduling. A large-scale mixed integer formulation is presented for the simultaneous matching of inbound cars to outbound trains, assignment of switch crews, and assignment of yard tracks along with solution algorithms. Yagar and Saccamanno [66] describe a dynamic programming application applied at a yard for Canadian National.

FURTHER READING AND OTHER TOPICS

A number of survey articles have been written describing research and application of OR methodologies in the rail industry (Cordeau *et al.* [24] is a recent example). For example, a recent tutorial of various methods applied to numerous rail problems can be found in Ahuja *et al.* [67]. Classic surveys in rail optimization can be found in Assad [68] and Haghani [69]. Recent summary discussion on optimization in rail have been published in Newman *et al.* [70], a broader discussion of long-haul freight transportation is in Crainic and Hall [71], and specific discussion of intermodal in Crainic and Kim [72].

Numerous other topics in OR and rail outside of service design and asset management have been pursued by researchers and applied in practice. For examples, Gorman [73,74] discusses pricing optimization and yield management in the rail context. Gorman and Kanet [75] and Podofilini *et al.* [76] explore line maintenance planning and scheduling. Finally, broader questions of modal choice and rail in the context of national transportation network design has been researched by Gorman [77] and Crainic [78].

New topics in rail research are emerging. Future topics of interest could center on topics such as mode sustainability and fuel conservation, security of rail and port operations, internationalization and containerization, public–private partnerships in rail

infrastructure investment, line capacity with satellite tracking and control, and the freight and passenger rail interface.

OPERATIONS RESEARCH FOR FREIGHT TRAIN ROUTING AND SCHEDULING

STEVEN HARROD
MICHAEL F. GORMAN
Department of MIS, Operations
Management, and Decision
Sciences, University of Dayton,
Dayton, Ohio

Although a very old technology with many traditions, today, freight railway managers make extensive use of operations research to address complex operations problems. This article surveys planning and control of freight train movements upon the rail network frequently referred to as the *operating plan*. We describe the typical practical decisions faced by railway management given a fixed infrastructure, and systematically describe relevant operations research theory and practice. The planning and control of assets such as locomotives and crews are typically subordinate decisions to the train movement plan and are not addressed here. We do address these topics in our companion article (see ***Operations Research Approaches to Asset Management in Freight Rail***) along with the long-term planning of lines and yards. Notable prior surveys of operations research applicable to freight rail are Cordeau *et al.* [1], Haghani [2], and Assad [3]. A higher abstraction of operational planning would be the determination of what services to offer and at what price to offer them. We do not address this topic directly, but instead recommend Crainic [4]. Although passenger train operations share many operational problems with freight rail, many of the procedures described here are irrelevant to passenger services and we refer the interested reader to Caprara *et al.* [5], Huisman *et al.* [6], and Kroon *et al.* [7] for literature on passenger services.

In addition to surveying recent literature, this article organizes the literature according to the alternative operational strategies

found in rail freight. In the next section we describe the significance of rail freight and describe significant technology differences between systems. In the section titled “Service Design,” we define service design and the activities that are typical of a block car routing strategy. A single car routing strategy is more common in high frequency hub and spoke services and is described in the section titled “Individual Car Routing.” We present scheduling algorithms and performance estimates for *ad hoc* dispatching without predefined train paths in the section titled “Timetable-Free Dispatching,” and a novel classification scheme for the decision variable structure of train pathing problems in the section titled “Timetable Generation.” In the section titled “Conclusion and Future Trends,” we conclude with comments on likely future operations research topics in freight rail.

SIGNIFICANCE AND DESCRIPTION OF RAIL FREIGHT OPERATIONS

Freight rail is an important and growing component in the world’s freight transportation infrastructure. In the United States, for example, ton-miles carried by rail have increased from 27% of all modes ton-miles in 1980 to 39% in 2007, and have doubled in absolute figures [8]. In Europe, rail freight captured only 17.3% of all modes ton-kilometers in 2006, but grew in absolute figures at an annual compounded growth rate of 2.2% from 2001 to 2006 [9].

Other technology and traffic conditions also motivate differences between typical North American and European applications of operations research to rail freight. The European network is typically limited to trains of 750 m length, with some exceptional trains of 1 km length, but the North American network regularly operates trains of 2.29 km (7500 ft) and some operations now support lengths of 3 km (10,000 ft). The mix of freight traffic in Europe contains a higher proportion of priority freight than the North

American market. According to Vassallo and Fagan [10], in 2000, coal accounted for 23% of North American railway and highway ton-kilometers, but in Europe it was only 1%. Finally, European rail freight must integrate with a dense and punctual passenger rail service. According to the International Union of Railways [11] the ratio of passenger kilometers to ton-kilometers in Europe in 2008 was 0.15, but in North America it was only 0.004.

Freight trains may be classified under three types: unit, loose car, and dedicated. Unit trains are effectively permanently coupled trains that make cyclical trips carrying commodities such as coal or grain. Dedicated trains are trains composed of one car type usually providing a carefully structured level of service, but they may consolidate traffic and require some switching. Examples of dedicated trains are solid trains of frozen concentrate orange juice between Florida and New Jersey, intermodal trains between Los Angeles and Chicago, and imported automobiles shipped from Pacific ports to inland distribution centers. Loose car or carload trains move a broad spectrum of mixed freight in a vast array of car types to and from every location on the network. Customers load and unload one or more cars at their private sidings. This requires frequent switching of cars between trains and adjustment of schedules to individual customer requests and levels of business activity. Loose car operations present very complicated combinatorial problems and consequently are frequently an operations research topic.

SERVICE DESIGN

The activities of train frequency setting and car routing are collectively categorized as *service design*, and are usually strategic, longer time horizon decisions. Medium time horizon or tactical decisions are composed of setting train departure and arrival times, and revising car routings to agree with train schedules. Short-term or operational decisions consist of assigning specific cars to specific trains, determining of specific train paths on the available tracks (and consequent further revision of specific timings),

and revising en route train paths in response to network delays. These plans are consolidated into the daily operating plan.

Typically in the literature a “train schedule” establishes the train routes (the set of lines and yards to traverse), train frequency and time at origin, destination and intermediate yards, and cars handled by a train (picked up or dropped off at intermediate yards). For example, Gorman [12,13] uses genetic search algorithms to determine the operating plan for intermodal services at BNSF predecessor Santa Fe. The train schedule does not establish an operational train path on the network as described in the section titled “Train Pathing”, but it does affect connection times for cars and, thus, service quality.

Cars may be individually routed to their destination on the next available train, or they may be held and consolidated to travel to common destinations together. The latter method is called anticipation classification or *blocking*, and dominates service design in North America not only because coupling and uncoupling is labor intensive, but also because the North American coupler design makes hump yard classification of some car types inadvisable. The challenge in service design is to create large enough blocks and trains to allow for economies of scale, but avoid excess handling and frequent train starts, while remaining feasible from both a yard and train capacity perspective and a customer service perspective.

The combined problem of assigning cars to blocks, assigning blocks to trains, establishing train frequencies, and setting departure times is vast in size and exceeds any current resolution capability. Instead, the problem is decomposed by activity and solved iteratively. Typically, the blocking plan focuses on minimizing handling costs and the distance traveled. The train plan brings service frequency and timing into account, thus including car delay costs and customer service considerations. Given a set of demands that must be serviced, the optimal train schedule and blocking plan minimizes cost of service subject to meeting customer service requirements. Ahuja *et al.* [14] offer a detailed explanation of these various levels of planning

in North American practice. Haghani [15] demonstrates in an early model formulation that significant performance improvements may be achieved by combining the car routing and train frequency problem.

Anticipation Classification or Blocking

In North America, rail freight's primary competitive advantage of rail is low cost over long distances, and blocking of cars supports this service strategy. Consequently, all of the literature in this section refers to North American applications. Anticipation classification or blocking reduces the frequency of hump yard classification, but incurs some additional delay while cars accumulate to form a block. Under this strategy, cars are consolidated and coupled by final destination very early, and a block is defined as a set of rail cars ready for departure from the same origin to the same destination.

Take, for example, a shipment from Bangor, Maine, to Louisville, Kentucky. It could be placed in a small block to Louisville, and not be reclassified, or could be placed in a large block to Cincinnati, where it would have to be switched to another block destined for Louisville. In the direct block, the car would experience a longer departure delay waiting for cars to form a block (because there is a limited amount of traffic between these two cities). In the separate blocks through Cincinnati, the car would enjoy frequent departures, but incur additional switching cost.

At the Canadian Pacific Railway, Ireland *et al.* [16] first define optimal blocks as a function of aggregate cargo flows, then define train schedules (departure times, not train paths) to support these blocks, simulate the schedules for reliability and yard inventories, and finally assign locomotives. Infeasibility or discovered alternatives at any stage may cause a revision of the prior activity solution. Crainic *et al.* [17] present an alternative sequence for Canadian National Railway, where train frequencies are defined first and then the blocking policy is defined upon the train schedule. The algorithm initializes at a high train frequency, successively reduces frequency, and generates a new blocking plan at each iteration, stopping at a predefined objective change. Newton *et al.* [18] focus

solely on the blocking activity without consideration of the train frequencies. Jha *et al.* [19] address the operational decision of assigning specific realized blocks to scheduled trains, where both the blocking policy and train schedule are predefined.

Blocking introduces a number of integer variables in formulations. For example, the assignment of blocks to trains is constrained by train capacity, potentially forcing a choice between dividing a block, dispatching a light train, and dispatching a heavy, underpowered train. The latter option affects over the road performance and introduces delay to other trains on the route. In addition, sometimes minimum block sizes are established, which imply some origin dwell time to accumulate rail cars. As blocking policy becomes more aggressive, car delays at the origin increase, larger yards are necessary to inventory cars, and car cycle times increase.

The blocking problem is a fertile ground for solution algorithms and strategy. Bodin *et al.* [20] present a nonlinear formulation that presumes a fixed train schedule, but is unable to solve practical problem sizes. Keaton [21] provides practical tips on the application of Lagrangian relaxation to the combined train frequency and car routing model. Martinelli and Teng [22] use artificial intelligence to generate fast solutions to an experimental example of the block to train assignment. Marín and Salmerón [23] compare simulated annealing, tabu search, and descending contour search heuristics for a generalized railway network problem, and Marín and Salmerón [24] develop statistical measures of the quality of the solutions generated.

Huntley *et al.* [25] present an actual implementation of simulated annealing to the weekly block scheduling problem at CSX. Ahuja *et al.* [26] describe very large-scale network search algorithms for blocking problems implemented at CSX, Norfolk Southern, and BNSF railways, under either unconstrained or predefined train frequencies. Kwon *et al.* [27] explicitly consider shipper delivery time expectations and train lengths, and apply a column generating solution algorithm. Barnhart *et al.* [28] apply both Lagrangian relaxation and column generation.

Individual Car Routing

Rail freight services in Europe typically cover much shorter distances and require a more punctual, responsive service. The infrastructure and dense passenger service schedule support and, in some cases, require operation of shorter, more frequent freight trains. There are also fewer technical limitations to the hump yard classification of cars in Europe. Consequently, blocking is less advantageous.

If blocking is dispensed with, a more even distribution of tonnage across trains may be achieved. Individual car routing allows smaller fractions of train capacity to be allocated. Ceselli *et al.* [29] describe the Swiss SBB Cargo Express service, which provides car load freight service within Switzerland on an overnight delivery cycle. They describe a hub and spoke network with two yards (hubs), and formulate a combined service design problem that assigns cars to trains, determines the train schedules (but not the dispatch paths), and respects capacity limits at the yards.

None of the models and service design methods yet described consider the return routing of empty cars. Campetella *et al.* [30] include the movement of empty cars in their solution to train frequency and car routing on the Italian FS network. The objective function is nonlinear, where costs decline as train frequency increases on a route because of a weighted improvement in the quality or reliability of service. The cost function is concave and the constraint set is linear and integer. Solutions from a genetic algorithm are described.

TRAIN PATHING

A train path is the complete authority for a train to use tracks and sidings from its origin to its destination. Track is usually divided into discrete controlled segments called *blocks*, and a train path is then a list of authorized blocks and times. The more highly utilized a network, and the more that punctual operation is desired, the more critical it is to configure and validate train paths in advance.

Train pathing is typically performed at either a strategic level or an operational level. If train paths have been configured and distributed in advance, then the trains are operating under a timetable. In the absence of a timetable, train paths are determined by dispatchers as the trains are en route. White and Krug [31] call this “timetable-free” or “improvised” operation.

The distinction between these two scenarios is increasingly blurred. Modern algorithms and computers allow computation of revised timetables (of varying quality) on demand. Many signal control systems provide automatic route setting functions that arrange groups of train paths within a limited area and time horizon. See Pahl [32] for a description of route setting and signaling technologies. Therefore, to provide a clear definition, we define timetable authority as any scenario in which a train possesses a defined and validated path before entering the network. A railway is operating under timetable if the majority of its trains operate under timetable authority.

The distinction between timetabling and “rescheduling” or “tactical” train path scheduling is largely unnecessary, as both activities require the same problem data, have the same constraints, and typically have similar objective functions. The primary difference is one of application and solution quality. Rescheduling typically must be performed quickly, and so the emphasis is on heuristics and quality suboptimal solutions returned in seconds. Consequently, we group these papers together.

Once again, environmental and market factors encourage distinct preferences in train pathing. European networks intermix freight trains with passenger trains and stringent punctuality is maintained. In addition, many of the national networks have transitioned to “open access”, where the management of the rail network and the operation of trains fall under separate business entities. Competing train operating companies share the same rail network. Operators negotiate and contract for train paths months in advance. Penalties are assessed for failure to provide a train path and failure

to conform to a train path (operator fault). Consequently, timetable operation is typical.

In contrast, vertical integration of infrastructure and operations is still the rule in North America. Traffic fluctuations lead to various train delays and cancellations. For example, blocking policy may lead to an inadequately powered train, which then has difficulty accelerating to scheduled speed. Passenger trains which share the freight rail network have considerable amounts of buffer time or “slack” included in their schedules to allow flexibility for these events. Consequently, although certain patterns may recur from day to day, the train paths are determined dynamically according to relative train priorities, over a shorter time horizon and smaller network segment, and not according to a predetermined timetable.

Timetable-Free Dispatching

Under a timetable-free operating plan, train paths and sequencing are determined by dispatchers as trains arrive within their region of supervision. Excepting passenger and select time sensitive freight trains, dispatchers have the authority to hold trains indefinitely at sidings according to their experience and judgment of what is feasible and best for the operating plan. It is very typical in these operations to find that locomotives, and train lengths are pressed to their limits, which further leads to variability in trip times. This variability in trip times makes adherence to a timetable very difficult, and thus argues for a timetable-free operation.

Under timetable-free operations, transit time over a route is not fixed and a variety of empirical and statistical methods are used to forecast trip times. Gorman [33] reviews a representative sample of North American lines and performs a linear regression of train delays as a function of dispatch conditions. Krueger [34] discusses a number of estimators of network capacity under an unscheduled, manual dispatch policy. Abbott [35] calculates the loss of train paths and incremental delay resulting from mixing high-speed and regular train traffic on a single direction route.

Hallowell [36] estimates delays to trains on either single or double track from simulations of a range of train frequencies and departure time variances under an advanced meet/pass planning algorithm. Carey and Kwieciński [37] devise probabilistic estimates of train delays on single direction lines as a function of dispatch headways and signal headways. Harker and Hong [38] devise probabilistic estimates of mean and variance of train delays on mixed single and double track lines where trains depart with some known variance around a scheduled time.

Dispatch decision making under timetable-free operation frequently requires the arbitration of conflicts between pairs of trains. Sauder and Westerman [39] describe a very early computer-aided dispatching system that estimated the delay cost of a set of dispatching alternatives. In many cases train values may be defined by linear functions, and thus the dispatching decision space is convex. Kraft [40] takes advantage of this property with a branch-and-bound decision algorithm that seeks to eliminate inferior dispatch options early in the decision process.

Jovanović and Harker [41] consider in detail what factors should be included in a dispatch objective. In particular, they express concern that the sum of weighted train delays is too narrow an objective for efficient dispatch. Şahin [42] models the dispatcher’s cognitive decision in the meet/pass planning problem and demonstrates that computer algorithms can significantly improve the quality of dispatching plans. Mills *et al.* [43] enhance the dispatch decision to consider fuel consumption. They propose both discrete-time network and nonlinear real-valued time models, and find that the simpler discrete-time model returns high quality solutions. Although intended for dispatching, this last model could also be classified as a timetabling tool.

Timetable Generation

The earliest timetabling models and solution methods were limited to long-term planning both because of the time required to obtain a solution, and because the solutions were frequently imperfect and required manual revision. Szpigel [44] is frequently cited as the

earliest example of global timetable optimization. That model minimizes the weighted sum of train transit times on a single track line, but does not constrain the capacity of sidings or stations. Direct manipulation of the integer variables is avoided by dynamically adding constraints at the branches of the solution tree, an application of the method of Greenberg [45].

Two model forms appear frequently. The first is the binary integer occupancy problem (BIOP), where a discrete-time network is defined and each binary decision variable represents the potential occupation of a track segment by one train during one discrete-time interval. The second is the mixed integer sequencing linear program (MISLP), where timing variables are real valued, and binary variables decide the precedence of pairs of trains at conflicted track segments. Both these model classes may be viewed as responses to the lack of siding or station capacity constraints in Szpigel. The BIOP formulation first appears in Mees [46], along with an approximate solution algorithm based upon Lagrangian relaxation.

The MISLP formulation first appears in Carey [47,48]. However, this model is too complex for optimal solution, and the authors describe algorithms that schedule trains sequentially and iteratively, with methods derived from observed practice of human dispatchers. Kraay and Harker [49] formulate a MISLP model with a nonlinear objective that considers the crew schedules and car blocking connections typical of North American operations. A prerequisite to the application of this model is the abandonment of timetable-free operation [50]. North American railways were unwilling to make this change in the 1990s; consequently, this model was not placed into service. Higgins *et al.* [51] formulate an MISLP model with a nonlinear objective of tardiness and fuel costs and decompose the problem into meet/pass planning and timing steps.

An open access network motivates Brannlund *et al.* [52] to describe sequential, iterative solution procedures for another BIOP formulation. In this article, Lagrangian dual variables serve to estimate the value or market price of a train path. Caprara

et al. [53] formulate a similar BIOP model, where train path enumeration is integrated within the primal problem. An application of this model specific to freight rail appears in Cacchiani *et al.* [54]. Borndörfer *et al.* [55] enhance the formulation of Caprara *et al.* to consider clique sets of mutually exclusive train path segments. Timetables are generated iteratively as part of a Parkes “i-bundle” auction of train paths.

Computing power and solution algorithms for multicommodity flow networks have improved significantly in the last decade, leading to more aggressive models and problem sizes. Ahuja *et al.* [14] present a BIOP model along with a greedy solution heuristic and a constraint tightening heuristic. Zhou and Zhong [56] apply an MISLP formulation to a double track high-speed railway in China, and develop a Pareto optimal frontier for two distinct objectives: minimization of the variance of interdeparture times and minimization of the total travel time. Harrod [57] visualizes the railway network as a hypergraph and formulates a binary decision variable model that constrains transitions between track segments over a time interval. Harrod [58] demonstrates that increasing the speed of priority trains relative to other trains increases the number of possible train paths on a single track line. Caimi *et al.* [59] demonstrate that the feasible solution set of a BIOP formulation may be reduced by deleting train paths that are dominated by other paths.

In recent years, the algorithms and available computing power have improved sufficiently that real-time, dynamic timetable solutions are available. These are usually presented as methods to respond to train delays and network disruption, but they also support impromptu additions of extra trains to existing timetable dispatched networks. Törnquist and Persson [60] address the rescheduling problem with an MISLP model, and find that the best solution strategy is to bound the problem by limiting the number of changes to relative train priorities. Later, Törnquist [61] found that local optimization over a rolling time horizon was competitive to optimization over the full time horizon.

Alternative graph theory has played a role in dynamic rescheduling. Mascis and Pacciarelli [62] present an algorithm called *Avoid Maximum Current Cmax* (AMCC), which they find suitable for the solution of train timetabling problems formulated as alternative graphs. Mazzarello and Ottaviani [63] apply this formulation and algorithm to dynamic rescheduling after delays on two Netherlands Railways examples. D'Ariano *et al.* [64] extend the AMCC algorithm further by compiling sets of "static implications," or sets of implied constraints, and demonstrate a 120 s solution time on problems drawn from the Netherlands Railways Schiphol district.

Lastly, the periodic event scheduling problem (PESP) should be mentioned. Primarily intended for passenger railways with cyclical schedules, it could also be applied to cyclical scheduled freight operations or networks, where freight paths must integrate with cyclical passenger schedules. The method originates with Serafini and Ukovich [65] and is first applied by Odijk [66]. Notable applications of PESP include the Netherlands Railways Design of Network Services (DONS) timetabling system [67], which was the 2008 Franz Edelman Award recipient [7], and the Berlin U-bahn network [68].

CONCLUSION AND FUTURE TRENDS

The service design problem, which combines both car classification and train scheduling, is at the heart of rail operations planning, and is one of the most difficult. The problem is nearly always expressed as a very large-scale dynamic network. The magnitude of these problems and their economic significance have motivated many fundamental achievements in operations research, such as network flow theory, column generation, and alternative graph theory. When the problems exceed reasonable solution capabilities, they are frequently decomposed into the blocking plan problem, the train frequency problem, and either the timetabling or dispatching problem. These problems are interrelated, and the unique strategic and environmental

concerns of each railway determine the order of their solution.

Significant technological and economic conditions differentiate the most common practices in North America and Europe. Long distances, tolerant clearances, long train lengths, and a preponderance of coal and grain motivate North American operators to emphasize consolidation of car loads into blocks. Economies of scale are more important than punctuality, so that stochastic analysis of transit times dominates over timetabling. We survey literature that addresses the blocking problem typical of North America and the dispatch problem of "meet/pass" planning, where trains proceed across the network without a predefined train path or timetable. The very large scale of blocking (network) problems motivates applications of Lagrangian relaxation, column generation, and genetic search.

European railways attract higher value shipments, operate over shorter distances, and must integrate freight trains with dense passenger services. Punctuality is emphasized and timetabled train paths are enforced. It is more common to route shipments as individual car loads through a hub and spoke system, without blocking. Timetabling, the advance determination of train paths, is common for freight traffic in Europe. This is frequently mandatory in order to share a railway line with scheduled passenger service, and also provides the benefit of higher service quality. The majority of timetabling models may be categorized as either managing the occupancy of discrete-timed track segments with binary variables or equating the resource priority of trains with binary variables and the timing with real-valued variables. On lines dominated by cyclical passenger traffic, the periodic event scheduling problem formulation may also determine freight train paths.

Research in this area has focused almost exclusively on planning, whereas only little research has been conducted on operating plan execution. Since operational flexibility can be valuable, and traffic demand is notoriously volatile and hard to predict, on-the-fly

schedule adjustments are common. For example, when disturbances occur to car routing plans or train frequencies, should an attempt be made to return to the prior plan, or should an alternate plan be formulated?

Commercial vendors have made significant advances in their train pathing and dispatch route setting systems, but little has been published on these systems. In at least one instance known to the authors, there was a desire to protect commercial intellectual property. Automated route setting systems increasingly can optimize groups of trains over longer time horizons according to defined global objectives. As these systems become more sophisticated, the distinction between meet/pass planning and network train pathing (timetable design) narrows.

Improvements in signaling and communications technology are underway in both North America and Europe that will expand the range of problems to be addressed by operations research and/or eliminate or revise standard problem constraints. In North America, Federal law asserts that positive train control, the direct monitoring of train positions by live communication links, shall be required within 10 years. On some networks this will change dispatch strategy. Long-term European plans are to standardize the signaling systems that currently limit circulation of locomotives. This will eliminate many constraints on train frequency and international services.

OPERATIONS RESEARCH IN AUSTRALIA

ERHAN KOZAN
School of Mathematical Sciences,
Queensland University of
Technology, Brisbane,
Queensland, Australia

Operations research (OR) was initially introduced to Australia from Britain in about 1942 by the Australian Army. Early studies were restricted to weapons research. Later studies were in administrative and logistical areas, which were also valuable to the war effort. After the war, OR activities in the army were allowed to run down and it began to be used by civilians in the 1950s. According to Mellor [1], the first two civilian OR records were by Bowen (1948) on "Operational Research into Air Traffic Problem," and Muncey and Hutson (1953) on "The Effect of Floor on Foot Temperature."

In the 1960s, OR practitioners set up local OR groups in Melbourne and Sydney and this pattern was repeated in other major urban centers including the smaller cities of Wollongong and Newcastle, which had substantial industry. Informal links between the Melbourne and Sydney groups led to the establishment of the Australian Joint Council for Operational Research (AJCOR). As a result of a meeting held in November 1971, the council of the Statistical Society of Australia agreed to the initiative of its OR section to form an autonomous and national society. Then on January 1 1972, members of the OR section, also being members of AJCOR, agreed to have AJCOR superseded by a new national society which was to be named the Australian Society for Operations Research Incorporated (ASOR) [2].

Currently ASOR has about 250 members nationwide and like other national societies, it is affiliated to the International Federation of Operational Research Societies (IFORS). There are also a number of regional groups within IFORS. For instance, ASOR belongs

to Asian Pacific Operational Research Societies (APORS). ASOR serves the professional needs of OR analysts, managers, students, and educators by publishing a national bulletin and chapter newsletters. The society also serves as a focal point for operations researchers to communicate with each other and to reach out to other professional societies.

The Society's objectives are as follows:

- to foster the development of the science of OR;
- to promote the application of OR wherever appropriate;
- to facilitate the widest possible exchange of information and ideas on OR and related subjects;
- to define standards of proficiency in OR;
- to promote and facilitate the study of OR.

ASOR has had 18 presidents since 1971, their names and terms of office are given in Table 1.

The ASOR bulletin was founded in 1981 through the initiative of Ian Sadler, who was at that time the National President of ASOR. He launched a national newsletter to establish communication between chapters, and this eventually became the ASOR Bulletin. The first editor of the bulletin was Carlton Scott, who produced Volume 1 comprising three issues, in 1981. The ASOR Bulletin aims to provide news of ASOR activities, book reviews, Australian problem descriptions and solution approaches, and a forum on topics of interest to OR practitioners, researchers, academics, and students. The refereed articles are peer reviewed by at least two independent experts in the field. The ASOR Bulletin is published as four volumes per year in March, June, September, and December.

ASOR organizes its national conference every two years to keep up-to-date with OR issues in Australia and overseas. It is a good platform for discussions with practitioners

Table 1. Past Presidents of ASOR

President	Year	President	Year	President	Year
W.B Kennedy	1972–1973	J. Flanagan	1983–1985	E. Kozan	1998–1999
T.G. O'Meally	1973–1974	C. Pearce	1985–1987	C. Pearce	2000–2001
E.J. Buckman	1974–1976	P. Evans	1987–1989	S. Perkins	2002–2003
R.B. Potts	1976–1978	C.S. Newton	1989–1991	L. Caccetta	2004–2005
D. Atkinson	1978–1979	C. Malanos	1991–1993	B. Nath	2006–2007
J. Adams	1979–1980	P. Lochert	1993–1995	E. Kozan	2008–2009
I. Sadler	1980–1983	S. Weal	1996–1997		

and researchers. ASOR has organized 20 conferences since 1972 and rotated these conferences between the branches. Their distribution to the branches is as follows: South Australia, four times; Queensland, four times; Victoria, five times; New South Wales, three times, Australian Capital Territory, two times; and Western Australia, two times. Branches also hold one-day specialized workshops, industry workshops, and student conferences.

The Ren Potts award of the ASOR is intended to recognize individuals who have made outstanding contributions to theory or practice of OR in Australia. It is a national award restricted to Australian residents. Ren Potts was a leading researcher in traffic flow and later in other areas of OR, and was also very active in the formation and ongoing function of ASOR. He served as one of the first national presidents. The first worthy recipients of this medal were Dr. Bruce Craven, Prof. Charles Pierce, Prof. Pra Murthy, Prof. Jerzy Filar, and Prof. Santos Kumar. These awards are conferred at a special ceremony organized as part of ASOR's national conferences.

The ASOR National Council established an encouragement medal for new researchers, who have completed a research degree at the Master's or Ph. D. level in OR or in a related field with significant contribution to the advancement of OR from any Australian university. Normally those candidates will be considered who have completed all requirements for their degree between the two consecutive ASOR national conferences. The awards are conferred in a special ceremony held at the national conferences.

ASOR official web-site (<http://www.asor.org.au>) was set up in 2006 to present the latest information about the members, ASOR bulletin, constitution, by-laws, news, conferences, important events, and links.

The ASOR Inc. has fostered the profession of OR in Australia since 1972 and has served as a platform for exchange of ideas between practitioners. The initial enthusiasm evident in the 1970s has gradually declined and this has seen a movement away from the centralized OR group, although a number of large organizations such as BHP, Qantas, Queensland Rail, Commonwealth Bank, Shell, Queensland Transport, and AECOM still support small OR groups or individual OR practitioners. Developments in OR and the need for quantitative problem solving continue to flourish in the private and public sectors. OR continues to be applied under many guises with practitioners operating under related fields of practice, so that the application of OR is never diminishing.

Despite the loss of groups within the private and public enterprises specifically dedicated to OR, ASOR continued to grow in the 1980s and 1990s with an increasing academic component as time progressed. As the university sector expanded in Australia, OR became increasingly identified with academia. Practical issues in all areas of OR are addressed by our active researchers from the Commonwealth Scientific and Industrial Research Organization (CSIRO) and the Defense Science and Technology Organization (DSTO).

Many mathematics departments in Australia offer OR subjects at the undergraduate level and a doctoral program for graduate students in OR. Many OR subjects are also offered under different names within various departments of the universities. For graduate

students in OR, there are significant opportunities for part-time employment in many universities. In addition to providing income for the student, the experience gained by working on real problems can be invaluable to a future career in OR.

Till date, in the field of practice, many OR procedures have been standardized and practitioners commonly apply them. Practitioners within the private and public enterprises, who are affiliated with ASOR or similar groups within overseas parent organizations, continue to improve OR procedures thereby making strategic and tactical processes more efficient.

The importance of OR continues to grow since it is an indispensable tool for

solving difficult problems in the mining and resources sector, transport and communications, health and medicine, defense, and within the service sector. OR continues to play an important role in industry and will remain very influential in Australia's prosperity, particularly when considering the carbon-constrained future which lies ahead.

INTRODUCTION

Data analysis has become an essential part of today's world in the past decade. It is estimated that the amount of information in the world doubles every 20 months and the size and number of databases are increasing even faster [1]. With this explosion in data and information, data mining (DM) techniques have become ubiquitous with an upsurging interest from both academia and industry. The methods applied to extracting patterns from data have a long history for centuries, such as sorting data manually or using various hypothesis driven methods. However, it is extremely difficult to transform large volume of data into valuable knowledge by the traditional means of analysis in modern times. This motivates the development of modern DM methods, which are designed to discover meaningful representations or structures of data using pattern recognition, statistical, and mathematical techniques. Generally, DM techniques are first trained by sample data sets, and then scale the acquired knowledge up to large databases under the assumption that they have a structure similar to the training data. DM methods can be broadly categorized as either supervised or unsupervised learning. In supervised methods, the algorithm is provided with a set of training data whose class attributes are known. If the class information is not

available, unsupervised techniques can be employed, such that clustering algorithms are designed to discover underlying groupings of data instances, and rule association induction aims to explore associations and correlations among data instances.

Compared to DM, which is a relatively young discipline, the roots of operations research (OR) may be traced to early research of the optimization problems of transportation and mail system by the English mathematician Charles Babbage (1791–1871). Today, there are numerous well-developed OR techniques that are used routinely to solve problems in a wide range of application areas. OR and DM are two independent fields with distinct objectives. However, the intersection between OR and DM is also quite broad. Each of them could benefit from making use of the other. For example, OR techniques could enhance the efficiency of a DM process by embedding various optimization tools [2], and DM could provide a concise and meaningful data space that may greatly facilitate an OR process [3,4]. Recently, a growing interest in the integration of OR and DM can be observed in both OR and DM literature [5].

Primary tools of OR include optimization techniques, queueing theory, game theory, graph theory, probabilistic modeling, and simulation. The major focus of this article is the use of optimization techniques in DM. We review the state-of-the-art DM approaches and discuss how optimization techniques can be applied to solve these DM problems. The DM methods we discuss here include supervised methods, such as neural networks (NNs), support vector machine (SVM), K-nearest neighbor (KNN), decision tree, Bayesian learning, and unsupervised methods such as clustering and association rule induction. Although there are many other algorithms, these methods are among the most influential algorithms in DM research community. For each method, we introduce the basic concepts, review therecent advances on the algorithms, and

discuss the application of optimization techniques to these DM algorithms.

SUPERVISED LEARNING METHODS

Supervised learning approaches construct a predictive function from training data, which consists of sets of input–output pairs. They first find a global mapping between inputs and outputs, and then make predictions of new inputs that it has never seen by their generalization capability. Generally, a good generalization of supervised methods requires a training data set that is sufficiently large and representative of all cases so that a valid general mapping between outputs and inputs can be found. Supervised learning is the most frequently used paradigm in DM, and a large number of supervised learning algorithms have been developed in the last decades. The most popular ones are discussed in the following sections.

Neural Networks (NNs)

NNs, inspired by the structure of biological neurons, have been widely used to solve many classification problems where there exists sufficient amount of training data. NNs have gained this popularity owing to their powerful capacity to model extremely complex nonlinear functions and their relatively easy use with well-developed training algorithms. To train a NN, one first presents to the network a set of training data (a collection of input–output pairs), and then adjusts the weights of the NN in such a way that the prediction error between the desired and actual outputs of the training data is minimized. The mean squared error is the most commonly used cost function to represent prediction error, which is formulated by

$$E = \frac{1}{N} \sum_{i=1}^N (f(x_i) - y_i)^2, \quad (1)$$

where x_i, y_i are the input and output of training data, $f(x_i)$ is the output of NN with respect to the input x_i , and N is the number of training data.

To minimize prediction error, various update rules have been developed for training NNs, such as Perceptron learning rule and Widrow–Hoff rule [6]. Rumelhart *et al.* [7] proposed a pioneering work to apply a gradient descent–based optimization method to update the weights of a multilayer NN. This method was later on developed into the most well-known and widely used training algorithm of NNs called *backpropagation* (BP). BP employs error derivatives of a NN’s weights during training process and calculates how error changes as each weight is increased or decreased slightly. In general, the update rule of BP is given by

$$\omega_j = \omega_j - \alpha \frac{\partial E}{\partial \omega_j}, \quad (2)$$

where α is the learning rate, which controls the relative size of change in weights at every iteration, and $\frac{\partial E}{\partial \omega_j}$ is the partial derivative of error cost function E with respect to weight ω_j . BP has become quite popular in practice since it can often find a good set of weights in a reasonable amount of time. There have been many successful applications of BP in science, engineering, finance, and other disciplines [8].

Since BP training is a gradient descent process, it often gets trapped into local minima and thus is very inefficient in searching for the global optimum in a NN’s weight space. In recent years, genetic algorithms (GAS), as powerful global optimization tools, have been increasingly applied in optimizing a NN [9]. It is also very useful to solve the problems where gradient information is either not available or costly to obtain [10].

Simulated annealing techniques are also applied to gradient descent methods to help move out the local optima. However, these algorithms may experience cycling. An excellent alternative is to use tabu search introduced by Glover [11] in 1989. This method applies an iterative greedy search algorithm using the memory of past visited points. The tabu search imposes a “tabu” on some subset of the searching space so as to avoid making mistakes a second time. Battiti *et al.* [12] applied the concept of tabu search to train a NN, and their results demonstrated that

tabu search was effective in continuing the search after local minima and was also robust to random initial conditions.

Support Vector Machines (SVMs)

SVMs are an assembly of supervised machine learning algorithms with a rapidly growing spectrum of application areas, especially in DM. The widespread acceptance of SVMs are rooted in their robustness arising from the strong fundamentals of statistical learning theory (SLT) developed by Vladimir Vapnik [13,14]. SLT explains the learning process from a statistical point of view by empirical risk minimization and generalization. A major component of SLT is the Vapnik–Chervonenkis (VC) dimension of a statistical learning algorithm that reflects the algorithm’s capacity for learning complex data.

SVMs are most frequently used in classification problems [15,16]. The fundamental problem in SVM classification consists of two sets of instances as data points in $\mathfrak{N}^n$, which are referred to as *training* data with *positive* and the *negative* labels, and a decision boundary that separates them. Given positive and negative instances with nonoverlapping polytopes, the simplest form of a decision boundary is a hyperplane in $\mathfrak{N}^n$ that separates the two polytopes. One can find infinitely many such hyperplanes. However, STL shows that the hyperplane that maximizes its distance from the Closest point from these polytopes has the minimal empirical error and the best generalization capacity. This distance is referred to as the *margin*. The hyperplane is represented with a normal vector $\mathbf{w}$ and a bias term b , both of which can be multiplied by any scalar $\lambda \neq 0$ without changing the hyperplane. The distance of an instance $\mathbf{x} \in \mathfrak{N}^n$ from the hyperplane is $f(\mathbf{x}) = \langle \mathbf{w} \cdot \mathbf{x} \rangle + b$, where $\langle \cdot \rangle$ is the dot product. This distance is called the *functional* distance, whereas the (actual) *geometrical* distance is measured as $f(\mathbf{x})/\|\mathbf{w}\|$. The class of hyperplanes with a unit functional margin are called *canonical* hyperplanes and are used in modeling SVMs. For a canonical hyperplane, the geometric margin is equal to $1/\|\mathbf{w}\|$.

Given m pairs of training data $(\mathbf{x}_i, y_i)$, $i = 1, \dots, m$, where $y_i \in \{1, -1\}$ are the labels,

the hyperplane that maximizes the margin can be found by solving the following convex minimization problem:

$$\min_{\mathbf{w}, b} \left\{ \|\mathbf{w}\|^2/2 : y_i(\langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b) \geq 1, \right. \\ \left. i = 1, \dots, m \right\}. \quad (3)$$

This problem, which is also known as the *maximal margin classifier*, has a feasible solution when the data is separable, which usually is not the case in real-life problems. In the case of linearly inseparable training data, a slack term is added to each constraint and penalized in the objective as shown in the following problem, which is known as *soft margin classifier*.

$$\min_{\mathbf{w}, b} \left\{ \|\mathbf{w}\|^2/2 + C \sum_{i=1}^n \xi_i : y_i(\langle \mathbf{w} \cdot \mathbf{x}_i \rangle + b) \geq 1, \right. \\ \left. \xi_i \geq 0, i = 1, \dots, m \right\}. \quad (4)$$

Following Lagrangian dual of this formulation actually paves the way for nonlinear classification and SVM implementations.

$$\max_{\alpha} \left\{ \sum_{i=1}^n \alpha_i - 1/2 \sum_{i=1}^n \sum_{j=1}^n y_i y_j \alpha_i \alpha_j \langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle : \right. \\ \left. \sum_{i=1}^n y_i \alpha_i = 0, 0 \leq \alpha_i \leq C, i = 1, \dots, m \right\}. \quad (5)$$

In the solution to the dual problem, the instances with $0 < \alpha_i$ are the support vectors, and from the duality theory, we can determine the normal to the hyperplane as $\mathbf{w} = \sum_i y_i \alpha_i \mathbf{x}_i$. The instances that satisfy $0 < \alpha_i < C$ lie exactly at the margin with a target distance of $1/\|\mathbf{w}\|$. From complementary slackness, the constraints for these instances are binding without requiring any slack, from which the bias b can easily be calculated. The label for an instance whose class label is unknown can be determined with the

Figure 1. Linear and nonlinear SVM classification with highlighted support vectors on the class margins.

following function,

$$\text{class}(\mathbf{x}) = \text{sgn} \left(\sum_{i=1}^n y_i \alpha_i \langle \mathbf{x} \cdot \mathbf{x}_i \rangle + b \right). \quad (6)$$

The dual formulation and the distances between instances as dot products play the central role for expanding the capacity of an SVM classifier by implicitly mapping the data into a higher dimensional space. Such a mapping $\mathbf{x} \mapsto \phi(\mathbf{x})$ is done implicitly, since the dual formulation requires the dot product of the mapped points, $K(\mathbf{x}_i, \mathbf{x}_j) = \langle \phi(\mathbf{x}_i) \cdot \phi(\mathbf{x}_j) \rangle$. Here, K is the *kernel* and can take many linear and nonlinear forms as long as it satisfies certain geometrical properties in the mapped space [15]. Given the new nonlinear distances through the kernel function, the rest is to find a linear separation in the mapped higher dimensional space. The calculations of these distances are done implicitly by the kernel function. Some of the most frequently used kernel functions are linear, $\langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle$, polynomial, $(\langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle + 1)^d$, Gaussian radial basis, $\exp(-\|\mathbf{x} - i - \mathbf{x}_j\|^2 / 2\sigma^2)$ and sigmoid, $\tanh(\kappa \langle \mathbf{x}_i \cdot \mathbf{x}_j \rangle + c)$. In Fig. 1, examples of linear and nonlinear separation are given with highlighted support vectors on the class margins.

Although the underlying QP optimization problem for training SVM is convex with linear constraint, solving large problems become impractical with conventional quadratic optimization methods. Chunking and decomposition methods have been proposed to make SVM training practical [17,18]. The current

method used in most SVM implementations today is sequential minimal optimization (SMO). SMO is an extreme decomposition method that iteratively solves the QP problem two variables at a time, whose solution can be found analytically [19,20].

There are variations of SVM formulations based on penalization of the misclassification. The loss function in Equation (4) is known as *hinge-loss* or *linear* penalty, which can be replaced by a quadratic loss function. In this case, the penalty parameter is transferred to the objective in the dual, instead of appearing as an upper bound on the dual variables. Another possible variation is to maximize L_1 -norm of the margin, which provides a linear programming formulation with sparse solutions [21]. The sparsity of the solution is usually interpreted from a feature selection point of view. This linear formulation can be kernelized for nonlinear classification.

SVMs are extended to multiclass classification with one class against one class or one class against all classes training [22,23]. In *multiple instance learning*, the instances are replaced with bags of instances with asymmetrical classification rules, for which a number of SVM-based methods are developed [24–26]. These bags can also be classified symmetrically by a selective SVM method to obtain a large margin [27]. SVM concepts are also used for regression, in which case the class labels are replaced with real-valued predictions [28–30].

The applications of SVMs in real-life problems are overwhelmingly high in number

and wide in range. Some of these applications include handwritten digit recognition [31], object recognition [32], speaker identification [33], face detection in images [34], text categorization [35], pattern recognition [36], biomedical applications [37–40], and financial applications [41,42].

Decision Tree

Decision tree is a hierarchical tree structure that is used to classify data classes based on attributes of data instances. In a decision tree, nodes represent classification attributes and branches represent conjunctions of attributes that lead to those classifications. Given a set of training data, a decision tree can be induced in the form of a sequence of rules. Once a decision tree is formed, it can be easily used to classify unseen data instances based on their attribute values starting at the root node.

The key to build a decision tree is to choose attributes in order to branch. The objective is thus to reduce impurity or uncertainty in data as much as possible. A subset of data is pure if all instances belong to the same class. In general, decision tree algorithms are recursive. There are several popular algorithms that have been developed and performed well in decision tree regression, such as ID3, C4.5, and CART (classification and regression tree). The most well-known algorithm to generate decision trees is known as C4.5 [43]. It builds decision trees from a set of training data by using the concept of Shannon entropy [44], a measure of uncertainty associated with a random variable. On the basis of the fact that each attribute of data can be used to split the data set into smaller subsets, C4.5 examines the relative entropy for each attribute. The attribute with the highest normalized information gain is used to make a decision. Ruggieri [45] provided an efficient version of C4.5, called *EC4.5*, which was claimed to be able to achieve a performance gain up to five times to compute the same decision trees as C4.5. Yildiz and Dikmen [46] presented three parallel C4.5 algorithms which were designed to be applicable to large data sets. Baik and Bala [47] presented a distributed version of a decision tree by using an agent-based approach. The

designed agent generated partial trees and communicated the temporary results among them in a collaborative way. The distributed tree algorithm achieved a very good performance for several data sets collected from distributed hosts.

Decision trees provide an effective way for discovering meaningful patterns and classification rules for a data set. However, it might be impractical or impossible to construct a tree using all of the data instances for a very large data set. Even if an exhaustive tree may be possibly built, it might not be the best way to analyze the data. In this perspective, optimization techniques could play a valuable role in building accurate and concise decision trees from large data sets. One good example comes from the research of Quinlan [43] who proposed a method of selecting the best decision tree using the Minimum Description Length (MDL) principle [48]. A decision tree was first built using the standard DM algorithm C4.5, and then the optimal subtree structure was selected by the MDL, which selects a solution that minimizes the total number of bits needed to encode the tree and the description of the data given by the tree. The MDL-based optimization formulation offers a way to prune the designed tree structure and also avoids the problem of overfitting. Kennedy *et al.* [49] provided an example of applying GA to optimize a decision tree with respect to its classification accuracy. In particular, they encoded a decision tree as a linear array (chromosome), and prediction accuracy was the fitness function of GA. A standard crossover and mutation operations were performed to the chromosomes. The classification accuracy was monotonically increased after each generation of decision trees. Fu *et al.* [50] also applied GA to optimize a decision tree. The proposed GA-based method was shown to be robust to initial training samples, and outperformed the regular approach of building a decision tree using all the available data sets.

K-Nearest Neighbor (KNN)

The key concept of KNN algorithms is based on the assumption that data instances that are near to each other should have similar predicted values. In general, KNN methods

classify a data instance based on the majority category of its K closest neighbors. This means that an instance is assigned to the most common class amongst its K nearest neighbors. Any ties can be broken at random. If $K = 1$, an instance is just simply assigned to the class of its nearest neighbor.

The performance of KNN is highly affected by the choice of K . If K is too small, the prediction result might be very sensitive to noise points; if K is too large, the model tends to be inaccurate since too many points from other classes might be included. Another important issue of KNN is how to combine the class labels of nearest neighbors into prediction. As mentioned above, the simplest and basic method is to take a majority vote, however, problems may arise when the nearest neighbors are distributed widely or some classes dominate the prediction with more frequent samples. On the basis of the assumption that the closer neighbors are better candidates to indicate the class of a new instance, an enhanced approach is developed by assigning a weight to each neighbor according to its distance to the new instance. In particular, the weight of a neighbor is often defined as the reciprocal of its distance. The new instance is then classified to the class with the highest sum of weights. In addition, the distance measure is also essential to KNN approaches. Using a measure that is appropriate for the data at hand is important. A desirable measure should be the one that has a smaller distance value for the two instances with a greater possibility of having the same class. There are numerous similarity measures, which can be used to compute the distance between two instances, such as Euclidean distance, chi-square distance, and dynamic time warping.

Compared to other classifiers, KNN does not require a sophisticated modeling process and thus, is very easy to understand and implement. However, the cost of this is that KNN approaches are usually computational expensive since they have to compute distances to all training examples to classify a new instance.

Moreover, the classification accuracy of KNN can be severely degraded by the presence of irrelevant features. A good selection

of features could reduce the dimensionality of data, scale down the computation time, and, most importantly, improve the classification accuracy. Therefore, a key issue in much KNN research effort has been put into selecting appropriate sets of features. A good example of this field can be found in Chaovalitwongse *et al.* [51] who use a binary integer programming formulation to solve the feature selection problem of massive electroencephalogram data. This formulation actually represents a more general optimization framework of feature selection, which can be expressed as follows:

$$\begin{aligned} \min \quad & f(X) \\ \text{s.t.} \quad & L \leq \sum x_i \leq U, \\ & x_i = 1 \text{ if feature } i \text{ is selected,} \\ & 0 \text{ otherwise,} \\ & x_i \in X \text{ is the feature vector,} \end{aligned} \tag{7}$$

where U and L are the upper and lower bounds of the number of desired features, respectively.

Siedlecki and Sklansky [52] applied GA to performed feature selection for KNN classifiers. Each feature was encoded in a binary vector as a chromosome. If a bit is 1 then the corresponding feature was used in the KNN classifier; otherwise, the corresponding feature was unused. Each of the strings was penalized by the classification accuracy and the number of 1 bits (larger penalty for more 1s). The results indicated that GA-based optimization approach was effective to improve the performance of their KNN classifier for data sets with a large number of features (more than 20 in their studies). Punch *et al.* [53] expanded this 0–1 weighting approach into a 0–10 weighting structure for a better discrimination between the features. Their experiment results indicated that the enhanced KNN classifier worked better than the previous 0–1 approach.

Bayesian Learning

Bayesian decision theory is one of the most widely used statistical approaches to solve

problems in DM. The basic idea of Bayesian learning is built on the estimation of probability distributions [54], which can be described by the well-known naive Bayes probability model as follows:

$$P(H|D) = \frac{P(D|H)P(H)}{P(D)}, \quad (8)$$

where $P(H)$ is called *prior probability* of hypothesis H , which is the probability that H is correct before data D was seen; $P(D|H)$ is called *likelihood probability*, which is the probability of observation data D given that the hypothesis H is hold. $P(D)$ is called *prior probability*, which is the probability of witnessing D under all possible hypotheses. The ratio $P(D|H)/P(D)$ is often referred to as *irrelevance index*. If the irrelevance index is 1, any knowledge about H is not relevant to D . In other words, the occurrence of D is independent with the hypothesis H . Any value of irrelevance index below 1 measures the relevancy between D and hypothesis H . $P(H|D)$ is the posterior probability. It is the probability that the hypothesis H is true given that the data D occurs. On the basis of the naive Bayes probability model, a naive Bayesian classifier can be built by introducing some decision rules. The most commonly used one is called *maximum a posteriori decision rule*, which simply picks the hypothesis that is most probable.

The naive Bayesian classifier starts with a prior belief of an event, and then the belief is revised after observing the event. It has become popular because this process models the human belief revision system quite closely [55]. More importantly, the naive Bayesian classifier can be used to construct various powerful Bayesian networks, which have been widely used to solve many complex real-world problems [34,56,57]. For example, a Bayesian network could be built to represent the probabilistic relationships between diseases and symptoms. Given a symptom, the Bayesian network can be used to determine which disease it is with the highest probability [58].

Formally, a Bayesian network constructs a set of random variables and their joint probability distributions as a directed acyclic graph. Each node corresponds to a variable,

and each arc represents the conditional dependency between two variables. For some simplest cases, a Bayesian network can be specified manually. However, this becomes impossible for human beings when the network is too complex, which is often the case in real-world problems. In practice, the construction of Bayesian networks is often formulated as an optimization problem, where the computational task is to find a structure that maximizes a statistically motivated score function. The score is defined to describe the fitness of each possible structure to the observed data. Several existing approaches in use today solve the structure optimization problem by various heuristic search techniques, such as greedy hill-climbing and simulated annealing. One excellent example is from Heckerman *et al.* [59], who applied a hill-climbing search method to find the best network structures. The hill-climbing method starts with an initial network, which can be roughly constructed from expert knowledge. For each search step, it examines all possible variations of the current network obtainable by adding, deleting, or reversing arcs. The best variation with the highest score becomes the new current network. The process repeats until no structural variation improves the current score.

One problem of such local search techniques is it is computationally expensive, especially for a data set with large number of instances or attributes. Friedman *et al.* [60] proposed a faster searching algorithm by restricting the search space only to a small number of candidates for each variable. At each step, the learned network selects the best candidates for the next iteration within the restricted space. The method was evaluated by a number of large real-life data sets, and their results demonstrated that the method was significantly faster than many standard heuristic search procedures without loss of quality in the learned structures.

UNSUPERVISED LEARNING

Unsupervised learning is inspired by brain's ability to extract statistical patterns and recognize complex visual scenes, sounds, and

odors from sensory data. It takes root in neuroscience/psychology and is founded on information theory and statistics. Unsupervised learning is used to reveal and capture unknown, but useful data groupings in a given data set autonomously. The goal of unsupervised learning is to build meaningful representations of data sets for decision making, prediction, and efficient communication. Unsupervised learning methods have wide applications in biology, medicine, market research, and robotics, among others [61]. The two most popular unsupervised learning approaches are discussed in the following sections.

Clustering

Clustering deals with data that have not been preclassified in any way, and does not need any type of supervision during the learning process. It is an unsupervised paradigm which automatically assigns the input data into meaningful clusters based on their similarity. Therefore, the similarity measures between two clusters are essential to most unsupervised learning algorithms. There are many approaches to define similarity between data instances, such as Euclidean distance, Manhattan distance, Hamming distance, Mahalanobis distance, and angular separation. [62]. Owing to the variety of similarity measures available, one must carefully choose the measures, since they might highly influence the shape of clusters. For example, some instances may be close to one cluster according to one measure and further away according to another.

The performance of clustering algorithms can be evaluated by relationships, such as intraconnectivity and interconnectivity. Intraconnectivity is a measure of the density of connections between the data instances within a single cluster. A higher intraconnectivity indicates a better clustering arrangement in a sense that the data instances in the same cluster are highly dependent on each other. Interconnectivity is a measure of the connectivity between distinct clusters. A low degree of interconnectivity is desirable since it indicates that the individual clusters are largely independent of each other.

The goal of clustering is to group a given data set based on a certain measure of similarity. Optimization techniques play an important role in various clustering methods, since the problem is fundamentally to find the optimal groupings or relations for a given data set. Rao [63] was one of the pioneers to apply linear and nonlinear programming formulations to solve clustering problems in an efficient way. A comprehensive review of clustering and optimization formulations can be found in Hansen and Jaumard [64]. Among various clustering algorithms, the most well-known one is called *k-means clustering*. The objective of *k-means clustering* is to find k cluster centers that minimize a squared-error criterion function [61]. Cluster centers are represented by the gravity centers of data instances: that is, the coordinates of a cluster center are the arithmetic mean for each dimension separately over all the data instances in the cluster. The *k-means clustering* assigns each instance to a cluster whose center is nearest to it. Since *k-means clustering* generates partitions such that each pattern belongs to one and only one cluster, the obtained clusters are disjoint. In Dunn [65], a popular clustering algorithm called *fuzzy c-means* (FCM) was developed to allow one data instance to belong to two or more clusters. Each data instance is associated with every cluster by a membership function, by which it has a degree of likelihood to every cluster, rather than just being assigned completely to one cluster. For example, the data instances on the edge of a cluster may be in the cluster to a lesser degree than the instances around the center of the cluster. FCM finds the most characteristic data instance in a cluster to be the “center” of the cluster, and then assigns the grade of membership to each data instance in the cluster.

Sherali and Desai [66] formulated the clustering problem as a nonlinear, discrete optimization problem, and developed a global optimization approach to derive a global optimal partition. They also developed a global optimization algorithm for solving fuzzy clustering problems. The proposed global optimization-based fuzzy clustering

algorithm was validated by several standard data sets from the literature and the synthetically generated data sets for large problems. Their results demonstrated that the proposed algorithm exhibited better performance over the popular FCM technique. Bradley *et al.* [67] provided another optimization structure which uses a concave minimization model to find optimal clusters. Given m points in a n -dimensional Euclidean space R^n , a fixed number of cluster k , the centers of the cluster c are determined such that the sum of the distances of each point to a nearest cluster center is minimized. The general nonconvex optimization formulation can be expressed as follows:

$$\begin{aligned} \min_{C,D} \quad & \sum_{i=1}^m \min_l e^T d_{il} \\ \text{s.t.} \quad & -d_{il} \leq x_i - c_l \leq d_{il} \\ & i = 1, \dots, m \\ & l = 1, \dots, k. \end{aligned} \quad (9)$$

where x_i is the i th point out of m , c_l is the center of l -th cluster out of k , $d_{il} \in R^n$ is the dummy variable used to bound the components of the difference between point x_i and the center c_l , e is the unity vector. This general nonconvex problem was further reformulated into an optimization structure which minimizes a bilinear function using a k -median algorithm.

There are also several other important forms of clustering algorithms that can be distinguished from the literature.

- *Biclustering.* Biclustering is a clustering technique which allows simultaneous clustering of the set of samples and the set of sample attributes (or features). The basic idea of biclustering is that each cluster may be induced by a certain subset of sample features. Therefore, we may find an associated cluster of features for each cluster. The pair of a data cluster and its associated cluster of features is called a *bicluster*. Biclustering aims at partitioning a data set into biclusters. A variety of optimization methods have been used in biclustering algorithms to find the optimal partition. A comprehensive review

of biclustering can be found in Busygin *et al.* [68], which discusses the most widely used and successful biclustering techniques with an emphasis on their mathematical concepts and formulations. It is noted that a great variety of biclustering algorithms have been applied in bioinformatics [69] and text mining [70].

- *Network Clustering.* In many cases, data sets can be conveniently represented by networks or graphs. For these problems, network clustering can be used to construct network clusters for such data sets. A recent survey on network clustering methods can be found in Balasundaram and Butenko [71]. Usually, each data instance is represented by a vertex. Two data instances are connected by a link if they are similar or related based on certain similarity measure. The similarity criterion of a network model considers all data instances in a cluster as a whole and not just the pairwise relations between data instances. Network clustering has become an effective approach in clustering biological networks, such as protein interaction networks [72] and gene expression networks [73].
- *Hierarchical Clustering.* The clustering algorithms mentioned above, all partition data instances directly in a single step. On the other hand, hierarchical clustering attempts to find successive clusters using previously established clusters. Hierarchical clustering takes a series of partitions, which may separate the previous clusters successively into finer clusters, or combine a series of current clusters into larger clusters. Some well developed hierarchical clustering algorithms are Balanced Iterative Reducing and Clustering using Hierarchies (BIRCH) [74], Clustering Using Representatives (CURE) [75], a hierarchical clustering based on dynamic modeling called CHAMELEON [76], and an incremental hierarchical clustering algorithm called GRIN [77]. The major advantage of hierarchical clustering is that it does

not require the number of clusters to be known in advance. However, these methods suffer from their inability to perform adjustments once splitting or merging decisions are made.

- *Distributed Clustering.* Recently distributed clustering algorithms have attracted considerable attention to extract knowledge from large databases [78,79]. In many cases nowadays, the data are originally collected at different sites, and then brought together to extract information. These data sets are usually huge in size. Instead of being transmitted to a central site where we can analyze data by the standard clustering algorithms, data can be clustered independently on different local sites at first. In a subsequent step, the central site tries to establish a global clustering based on the local clustering results. This approach is computationally efficient, since local clusterings can be operated in a parallel way.

Association Rule Induction

Association rule induction is another popular unsupervised DM technique to discover interesting patterns extracted from a given data set. For each pattern, rule induction will statistically determine its accuracy and significance so that an end user knows how strong the pattern is and how likely it is to occur again. A typical association rule has a form as follows

$$X_1, X_2, \dots, X_n \longrightarrow Y_1, Y_2, \dots, Y_m, \quad (10)$$

where both of X , Y are combinations of binary attributes. To discover useful association rules from data efficiently, many optimization-based methods have been proposed in DM research community. “Apriori,” proposed by Agrawal and Srikant in [80], is the very popular algorithm to mine association rules. Apriori uses a breadth-first search strategy to count the support of itemsets and applies a candidate generation function to exploit the downward closure property of support. Since the first introduction of Apriori, various more efficient algorithms of

rule discovery have been developed, many of them share the same idea with Apriori in candidate generation, that is “if an itemset is not frequent, any of its superset is never frequent.” The Apriori algorithm is quite simple and easy to implement, thus Apriori-like algorithms are widely used in solving problems of association rule induction. Another interesting method was proposed by Rymon [81], who presented an optimization framework to discover minimal rules from binary data. The data set was encoded in a Boolean logic expression at first, and then logic minimization was used to simplify the Boolean logic expression to generate optimal rules.

CONCLUSIONS

In this article, we provided an overview of the most popular DM algorithms and paid particular attention on how optimization techniques can be applied to solve DM problems. Optimization techniques have been widely applied in DM, in both supervised and unsupervised methods. Optimization techniques can directly contribute to a DM model, and new DM approaches may be generated when they are combined with various optimization techniques. On the other hand, many DM methods are fundamentally optimization problems, such as SVM, clustering.

Optimization techniques can enhance a DM method by developing better solutions through various well-developed optimization tools. Many DM methods incorporate optimization as a part of the DM problem. A block diagram of a typical DM process and the application of optimization techniques in DM is shown in Fig. 2. In general, optimization techniques can significantly contribute to DM methods at three major stages:

- Optimal feature selection in data preprocessing step, which can significantly reduce the data dimensionality and search space for DM models.
- Construct optimization formulations directly in DM models, develop efficient optimization-based DM algorithms.
- Pick up the best patterns among a large number of candidates generated by DM models.

Figure 2. Block diagram of a typical data mining process, as well as the use of optimization techniques in DM at three major steps.

The use of optimization techniques can considerably improve the performance of DM in terms of efficiency, applicability, and accuracy. We provide the most distinct examples of optimization applications in DM and demonstrate how optimization frameworks can be formulated in DM structures. We believe that optimization techniques can play a critical role in providing better and faster solutions to DM problems. In conclusion, it can be stated that DM methods can also contribute to optimization problems in building efficient decision models by providing concise and meaningful representations for a given data set. It is noted that this area is relatively less studied compared to the numerous applications of optimization techniques in DM. The integration of optimization and DM in a closely complementary way constitutes a rich field of research for both OR and DM researchers.

TOWARD VALUE CHAIN MODELING

Operations research (OR) and management science (MS) have for many years played an important role in supporting forest products industry managers and public officials in their planning decisions. The industry covers many different applications, and the methodology used covers essentially all areas of OR/MS. Also, the industry is very important for several countries including Brazil, Canada, Chile, Finland, New Zealand, Russia, and Sweden. Depending on the country and company, the government, forest owners, and industries face different characteristics and slightly different models and methods are used. However, the basic properties and challenges are similar.

Several surveys exploring the different perspectives on the forest product supply chain can be found in the literature today. Some reviewed the contribution of OR to the forestry industry, focusing on issues related to forest management, harvesting, and transportation to wood-consuming industries [1,2]. Environmental and implementation

issues have also been included in the review [3]. More recently, these surveys were completed by including OR contributions to planning and distribution of forest products such as paper, lumber, engineered wood products, and biofuel [4]. In general, the quality of forest management and forest operations has an important and direct impact on the performance of the different wood fiber value chains. The *Handbook on Operations Research in Natural Resources* [5] presents articles showing multiple topics related to forest modeling, considering different hierarchical levels, spatial and environmental issues, and stochastic and multi-attribute approaches. A special issue of *INFOR* (Vol 3, 2010) also provides a number of applications of forest supply chains.

The literature in the forestry domain can be divided into two main categories. The first category focuses on the forest value chain, particularly forest management, harvesting, and transportation, and the second one focuses on forest products value chain planning for the different products/markets, such as pulp and paper, lumber, engineered wood products, and energy.

The outline of the article is as follows. In the section titled "Value Chains in the Forest Industry," we describe general aspects of value chains in the forest industry. The section titled "Planning Environment" describes the planning environment with strategic, tactical, and operational problems. In the sections titled "Forest Value Chain," "Pulp and Paper Value Chains," "Lumber, Panel, and Engineered Wood Value Chains," and "Energy Value Chains," each of the subchains is described. These are forest, pulp and paper, lumber, and energy chains. In the section titled "Discussion," emerging challenges are discussed.

VALUE CHAINS IN THE FOREST INDUSTRY

In order to transform raw materials from the forest into finished products, many

Figure 1. Illustration of the activities from forest to end customer.

operations have to be performed, and consequently, several enterprises and public organizations are involved. The ownership of the forest and the regulations to assess the wood fiber are fundamental characteristics of the different forest value chain structures that can be seen in the different countries around the world. The ownership of the forest will define how integrated the value chain is. When the forest is managed and owned by the public (e.g., under governmental management), the forest value chain is decoupled between the forest and the industry. When the forest is privately owned (e.g., industry or private owners), the forest value chain can be more or less decoupled. In the past years, whatever the structure of the forest value chain is, its activities have often been managed on the basis of local objectives and limited constraints. Today, because of greater knowledge about supply chain management, the involved organizations aim for higher coordination as well as increased value creation.

This complex set of entities that work together via relationships to create economic, environmental, and social values is known as a *value chain* or a *value creation network*. It encompasses all activities associated with the usage of the forest as well as its transformation into goods or services, from the raw materials stage to the end user stage, as well as the associated information flow. These activities are illustrated in Fig. 1.

The forest flows provide raw materials to the forest products industry. These wood fiber flows are mainly full-length trees, logs, or wood biomass. The fiber is transformed in different ways. From a modeling perspective, the transformative processes are either

defined as *one-to-one*, *one-to-many*, *many-to-one*, or *many-to-many*. Moreover, the processes in the forest value chain and the commodity business streams are not strictly defined; many recipes or cutting patterns can be used to provide the needed products. It is said that the processes are alternatives. However, it should be noted early that the value chain is divergent, that is, the number of products or stock keeping units (SKU) increases along the chain. Moreover, the value chain is mainly based on a push mode; that is, the production is supply driven rather than demand driven (i.e., pull based).

The value chains in the forest products industry include all forest owners, companies, and business units that are involved in the management of the forest, procurement, production, or transformation of a given forest product or service and its distribution to the market. They also extend to include recuperation value chains where products are either refurbished or converted into other products, for example, chemicals or energy. This can encompass those companies responsible for forestry operations, transportation, sawmilling, value-added production, pulp and paper, and so on.

The value chains extend in “time” and “space.” For example, the boreal forest may take up to a 100 years to regenerate and is normally widely spread. The value chains are composed of many units that can be associated to tightly connected chains; see Fig. 2. The forest value chain is responsible for managing the forest as well as for delivering the wood to the mills or the services to the population. The forest products value chains transforms the wood into products or services. It then sells and delivers the goods

Figure 2. The forest products value subchains.

to the markets. Moreover, it recuperates the products at the end of their useful life and then either refurbishes, converts into new products, or disposes of the products.

The ownership of the chain's units can be shared between public and private organizations (firms). The links between the units vary depending on country legislations and enterprise business models. The main business streams are pulp and paper (e.g., newsprint, fine paper, tissue, and packaging), wood products (e.g., lumber, panels, and engineered wood products for structural or appearance application), and energy (e.g., ethanol, pellets, and biogas). An emerging business stream that is not shown in the figure is known as the *green chemicals*.

The different wood product firms typically own a set of business units that are involved in the transformation and distribution of forest products. When such a firm owns units covering all operations from harvesting activities to distribution activities, it

is said to be vertically integrated. Certain large international companies, in addition to encompassing a wide range of activities, are also active in all of the different markets shown in Fig. 1. For example, Stora Enso, an international corporation with its head office in Finland, has many interrelated supply chains. This is the same for other International companies such as International Paper (USA), Abitibi-Bowater (CAN), UPM (Finland), Arauco (Chile), Fibria (Brazil), and Fletcher Challenge (New Zealand).

As compared to discrete manufacturing-based value chains (e.g., computers, cars, and appliances), forest value chains are complex adaptive systems that are strongly driven by socio-economical, technological, and environmental forces. This is because they rely on a natural resource that contributes to society in many ways. For example, in Canada, more than 300 collectivities are looking upon the forest and the forest products industry to provide jobs and economic development

opportunities as well as to mitigate climate changes through certified forest management (e.g., carbon sequestration) as well as low carbon footprint products (e.g., substitution to fossil-fuel-based products). This is also true for other countries including Sweden, Finland, Chile, New Zealand, and Russia.

The markets are worldwide and particularly dynamic at this time when emerging countries are increasing their consumption of fiber per capita (e.g., paper usage per capita, wood-based product per capita, wood-based energy per capita) and developed countries are moving toward the usage of more Internet-based media and communication. This is illustrated in Fig. 3. For example, in the pulp and paper industry and more specifically the newsprint segment, the North American market is decreasing while the Asian markets are growing. The dynamics of the markets raise challenging questions when it comes to redesign of the value chains through various international investments. Again, these decisions can be taken without an integrated view of the wood fiber supply and location as well as the market location and needs.

PLANNING ENVIRONMENT

Planning the forest value chain is a challenging process because of intrinsic characteristics of the resource, the transformative processes, and the market structures and behaviors. In the next sections, the different planning decisions are reviewed in terms of their strategic, tactical, and operational impacts. Following this, specific descriptions of the decisions taken in the forest value chains are described in more details illustrating the need for well-designed OR tools.

The planning of the forest value chain involves many decisions. These decisions are interrelated, because they involve planning a subset of activities that need to be synchronized with other activities out of the scope of the planning process. For example, harvesting decisions are to be synchronized with machine crew scheduling decisions and transportation decisions, and depending on the role and responsibilities of the value chain entities these decisions may be driven by different individual or groups. The decisions are also linked to time, as long-term decisions such as investment (e.g.,

Figure 3. Anticipated development of the global flow of wood fibers. [Source: Axelsson, Södra Cell AB from [6].]

mill investment and forest road investment) constrain the possibilities at the operation level. Finally, space distribution imposes decision synchronization; for example, forest management decisions have a strong impact on industry decisions; therefore, the location of the forest, industry, and market is critical and often has to be taken into consideration to make coherent set of decisions even though these are taken by different business entities.

To better understand the challenges of decision making in the forest value chain, we first review the nature of the decisions to be taken in terms of their strategic, tactical, and operational impacts. To manage the complexity and the links between all the decisions, hierarchical planning is used in the value chains [7].

Strategic Planning

Strategic, or long-term, planning in the forest value chain does indeed involve very long periods of time. For example, the rotation of forest growth can take more than 80 years, and a new pulp or paper mill is normally intended to last more than 30 years. On the other hand, at forest plantation in South America the rotation may be as short as 10 years. Thus, strategic decision making includes making choices related to forest management strategies, silviculture treatments, conservation areas, road construction, the opening/closing of mills, the location/acquisition of new mills, process investments (e.g., machines, transportation equipment, and information technology), product and market development, financial and operational hedging, planning strategies (e.g., make-to-stock, make-to-order, and cut-to-order), and inventory location (e.g., location of decoupling points and warehouses).

The planning approach chosen has a major impact on all investment decisions. For example, the capacity needs and the type of equipment required to support a make-to-stock strategy would be different than those needed to support a make-to-order strategy. Therefore, the planning approach defines important parameters with respect to the necessary technology, capacity, inventory

levels, and maximum distances to customers. Such decisions naturally involve evaluating how the investment will fit into the whole value chain, including deciding which markets to target, how the distribution of the products should be carried out and at what cost, and how the production units should be supplied with the necessary wood fibers (i.e., wood or pulp). Other elements, such as logistics infrastructure as well as energy and water supplies, might also be crucial as it is in the case of pulp and paper industry.

The type of forest land tenure may also affect the way supply chain strategic decisions are made. Wood could come from public lands, private lands, or both, with each type requiring different procurement programs. The types of logs and fibers also differ between regions, and different characteristics are better or less suited for different end products. Other factors may also have to be considered. For example, governmental rules governing the amount of forest land to be set aside for biodiversity purposes, recreational use, and/or carbon sequestration must be taken into account in any decision. The strategic planning of forests needs to consider the industries it supplies downstream, long-term environmental issues, and sustainability as well as its own silvicultural goals [8].

Tactical Planning

Following strategic planning, the next level in the hierarchical planning structure is tactical or mid-term planning. Tactical planning is slightly different depending on whether a forest management problem or a production/distribution planning problem is being addressed. In forest management, hierarchical planning approaches are widely implemented as they permit the strategic planning problem to be initially addressed without taking spatial issues into account. Once this has been done, the problem is then tightly constrained spatially. While strategic forest management planning problems generally span 100 years, tactical planning problems are often reviewed annually over a five-year planning period. Spatial aspects are fundamental in tactical planning. At the forest level, road building accounts for over 30%

of total harvesting costs in native forests. It has been shown that a correct planning approach needs to simultaneously tackle harvesting and road building to provide access [9]. Also, environmental issues that have become significant in the last few decades need to consider spatial issues very carefully. For example, in North America, total harvesting is allowed in small continuous patches, usually not larger than 40 ha.

In planning problems dealing with schedules and resources (e.g., supply/production/distribution issues), tactical planning normally addresses the allocation rules that define the unit or the group of units that is responsible for executing the different supply chain activities, or the type of resources or the group of resources that will be used. It also sets the rules in terms of supply/production/distribution lead times, lot sizing, and inventory policies. Tactical planning allows these two types of rules to be defined through a global analysis of the supply chain. Tactical planning also serves as a bridge between the long-term comprehensive strategic planning and the short-term detailed operational planning that has a direct influence on the actual operations in the chain (e.g., truck routing and production schedules). Tactical planning should also ensure that the subsequent operational planning conforms to the directives established during the strategic planning stage, even though the planning horizon is much shorter. Other typical tactical decisions concern allocating customers to mills and defining the necessary distribution capacity. The advanced planning required for distribution depends on the transportation mode. For example, ship and rail transportation typically need to be planned earlier than truck transportation.

Another important reason for tactical planning in the forest value chain is tied to seasonality, which increases the need for advanced planning. Seasonality has a great influence on the procurement stage (i.e., the outbound flow of wood fiber from the forests). One reason for this seasonality is the shifting weather conditions throughout the year, which can make it impossible to transport logs/chips during certain periods because of

a lack of carrying capacity of forest roads caused by the spring thaw, for example. In many areas of the world, seasonality also plays a role in harvesting operations. In the Nordic countries, for example, a relatively small proportion of the annual harvesting is done during the summer period (July–August). During this period, operations are instead focused on silvicultural management, including regeneration and cleaning activities. A large proportion of the wood is harvested during the winter when the ground is frozen, thus reducing the risk of damage while forwarding (or moving) the logs out of the forest. Seasonality can also affect the production stage (e.g., in Nordic countries, hardwood drying times can vary over the season) or the demand process (e.g., again in Nordic countries, most construction projects are not conducted during the winter period). In Chile, the harvesting season is centered on summer, the rainy winter season being more complicated as less costly dirt roads get muddy.

Budget projection is another area in which tactical planning is useful. Most companies execute an important planning task when projecting the annual budget for the following year, deciding which products to offer to customers and in what quantities. In the process of elaborating these decisions, companies need to evaluate the implications of their decisions on their whole value chain (procurement, production, and distribution) with the aim of maximizing net profits.

Operational Planning

The third level of planning is operational or short-term planning, which is the planning that precedes and determines real-world operations. The operational planning is really the planning process that fixes how and when the value will be captured. For this reason, this planning process must adequately reflect the detailed reality in which the operations take place. The precise timing of operations is crucial. It is generally not enough to know the week or month that a certain action should take place; the time period must be defined in terms of days or hours. Operational planning is usually distributed among the different facilities, or units in the facilities, because

of the enormous quantity of data that has to be manipulated at the operational level [e.g., number of stock keeping unit (SKU) and other specific resources]. In the forest value chain, many operational decisions need to be synchronized (e.g., harvesting, transportation, production, and distribution decisions). Different approaches are used to permit this; among all, information sharing or price-based mechanisms are the most commonly used.

Within the production process, one type of operational planning problem deals with cutting and must be solved by many of the wood product mills (e.g., lumber, dimension parts, and pulp and paper mills). Scheduling the different products moving through the manufacturing lines is also a typical operational planning problem, as is process control involving real-time operational planning decisions. Process control is particularly critical in the pulp and paper industry as the characteristics of the output products depend greatly on the precision of the chemical-fiber mix. Another type of operational planning problem deals with the problems related to transportation, specifically the routing and dispatching done at several points in the supply chain. For instance, it is necessary to route the trucks used for hauling wood from the forest to the mills or for shipping finished products from mills to customers or distribution centers.

Table 1 presents an illustrative summary of the strategic, tactical, and operational planning decisions needed in the pulp and paper industry. This supply chain planning matrix was proposed by Carlsson *et al.* [6] on the basis of a series of case studies conducted with the Swedish pulp producer Södra Cell.

FOREST VALUE CHAIN

The forest supply chain covers harvesting, storage, and transportation to terminals and mills (Fig. 4). It also includes the first conversion processes, for example, bucking and forwarding. Different modes of transportation (e.g., trucks, trains, and ships) are used to transport the various products from the forest units to the industrial mills.

The forest value chain must provide trees suitable for different uses. This involves

dealing with a variety of issues, ranging from strategic forest management (e.g., land management and silviculture treatments) to operational tasks related to harvesting and transportation. Forest planning means dealing with a very long-term planning horizon, anticipating natural disruptions like fires, considering multiple societal needs, and meeting industrial demands. Depending on the nature of the forest (e.g., species, age, soil, and plantation management) and the type of land tenure (e.g., public or private), the planning problems may differ from country to country and from region to region. For example, in Canada the forest is mainly Crown land and is managed by public officers. In Sweden, the forest is mainly owned by thousands of independent land owners who decide, following public regulation, as to which prescription to apply and when, to their land.

The forest value chain is a strategic component of the three main value chains described in this article (i.e., pulp and paper; lumber, panel, and engineered wood; energy). The various business units in the chain are typically extremely widespread geographically, since they deal with different operations (e.g., planting, thinning, road construction, harvesting, storage, and transportation). In the forest value chain, it is first necessary to solve the problem of allocating wood for different uses. In terms of economics, the problem then becomes a question of distributing the wood to the different chains. The long-term strategic decisions aim to attain societal targets that are defined in order to meet sustainable socio-economic development. Some of the strategies decided upon span several forest rotations, which means that some countries have to establish plans covering more than 100 years. Over time, these plans have a great impact on the quality and volume of the available fiber.

The forest is hierarchically planned from long-term strategic planning to mid-term tactical planning and short-term operational planning. Natural forests are composed of trees of different species, age, quality, and volume. They are managed according to the mix of their attributes. Plantation forests are more uniform in age, quality, and volume and

Table 1. The Pulp and Paper Value Chain Planning Matrix [6]

	Procurement	Production	Distribution	Sales
∞ Strategic	• Wood procurement strategy (private vs public land) • Forest land acquisitions and harvesting contracts • Silvicultural regime and regeneration strategies • Harvesting and transportation technology and capacity investment • Transportation strategy and investment (e.g., roads construction, trucks, wagons, and terminal, vessels)	• Location decisions • Outsourcing decisions • Technology and capacity investments • Product family allocation to facilities • Order penetration point strategy • Investment in information technology and planning systems (e.g., advance planning and scheduling)	• Warehouse location • Allocation of markets/customers to warehouse • Investment in logistics resources (e.g., warehouse, handling technologies, and vessels) • Contracts with logistics providers • Investment in information technology and planning systems (e.g., warehouse execution)	• Selection of markets (e.g., location, segment)—customer segmentation • Product-solution portfolio • Pricing strategy • Services strategy • Contracts • Investment in information technology and planning systems (e.g., on-line tracking system, CRM)
Tactical	• Sourcing plan (log class planning) • Harvesting aggregate planning			

	• Route definition and transshipment yard location and planning • Allocation of harvesting and transportation equipment to cutting blocs • Allocation of product/bloc to mills • Yard layout design • Log yard management policies	• Campaigns duration • Product sequencing in campaign • Lot sizing • Outsourcing planning (e.g., external conversion) • Seasonal inventory target • Parent roll assortment optimization • Temporary mill shutdowns	• Warehouse management policies (e.g., dock management) • Seasonal inventory target at DCs • Routing (vessel, train, and truck) • 3PL contracts	• Aggregate demand planning per segment • Customer contracts • Demand forecasting, safety stocks • Available to promise aggregate need and planning • Available to promise allocation rules (including rationing rules and substitution rules) • Allocation of product and customer to mills and distribution centers
Operational	• Detailed log supply planning • Forest to mills daily carrier selection and routing	• Pulp mills/paper machines/ winders/sheeters daily production plans • Mills to converters/DCs/ customers daily carrier selection and routing • Roll cutting • Process control	• Warehouses/DCs inventory management • DCs to customer daily carrier selection and routing • Vehicle loads	• Available to promise consumption • Rationing • Online ordering • Customer inventory management and replenishment

Figure 4. Illustration of harvesting, storage, and transportation activities.

typically provide one species. Silvicultural treatments may or may not involve flows of commercial fiber as opposed to harvesting, which always provides commercial flows. Estimating the basket of products to come out of the forest is very difficult and is often done through stochastic modeling of the forest growth and natural disturbances.

Forest Management

Strategic forest management places the emphasis on the relationship between decisions connected to forest use (e.g., harvesting areas, allocations, and silvicultural treatments) and their different socio-economic consequences (e.g., environmental problems, nondeclining yield, continued employment, forest access, and industrial competitiveness). Numerous models have been developed to aid forest managers and public forestry organizations in their decision making. Some of these models are based on operational research (e.g., harvest planning, road construction, and maintenance planning), while others are based on simulation

(e.g., simulations of growth or ecological impact). Economic models help to connect fiber availability to the value of the forest products. On public land, forest management regimes are established by the government. Moreover, on private land, several laws and regulations are also imposed by the government regarding forest management regimes. Since multiple criteria need to be considered during decision making, most governments and large companies use simulation to evaluate the impact of different forest management strategies.

Depending on the planning decisions to be taken, the forest is viewed from either landscape or regional standpoint. Forest planning includes deciding on silvicultural prescriptions to apply to one or many stands. The prescription includes a sequence of silvicultural treatments such as thinning and progressive or total cuts. These treatments have an impact on the growth of the forest and its sustainability; therefore, the set of possible prescriptions and treatments are normally defined by foresters. For example,

some thinning treatments result in higher quality trees.

During the 1970s and 1980s, linear programming (LP) models, such as the FORPLAN used by the USDA Forest Service, flourished [10]. LP models allow information about growth, biodiversity, spatial requirements, and requirements for protected area to be taken into account. In such models, forest management strategies are treated as constraints, though spatial constraints have not yet been considered. For example, these models normally include a set of nondeclining yield constraints.

With the advent of the geographical information systems (GIS) and the associated spatial data, integrated forest management and harvest planning practices have begun to show increasing concern for spatial relationships and environmental conditions. Particular issues of interest include promoting the richness and diversity of wildlife, creating favorable habitats for flora and fauna, ensuring the quality of soil and water, preserving scenic beauty, and guaranteeing sustainability. Tactical models seek to address these issues, implicitly or explicitly, by structuring the necessary constraining relationships and limiting spatial impact.

One of the primary ways by which spatial relationships and environmental conditions have been modeled at the tactical level is by using adjacency restrictions with green-up requirements. Specifically, a maximum local impact limit is established to restrict local activity for a given period of time. In the case of clear cutting, for example, this corresponds to a maximum open area, which is imposed on any management plan. Another important example for wildlife is the requirement that patches of mature habitats (i.e., contiguous areas of a certain age) must be maintained to allow animals to live and breed. To ensure this, potential areas must be grouped to form patches. A number of models incorporate the maximum open area and adjacency constraints. These models require binary variables to correctly describe the logical decisions and constraints. Both exact and heuristic methods have been proposed to solve these problems. The size ranges from a few

hundred to several hundred thousand management areas [11–13].

Fire is one example of a natural disruption that occurs in forests, thus affecting value chain planning. Fire management processes include both long-term integrated fire and forest management planning and the short-term dispatching of fire crews to stop fire from spreading. Fire management processes can vary from country to country, because of differences in climate, vegetation, and societal needs. The literature on the subject underscores the fact that fire can have a significant impact, both in terms of forest management and value chain planning. For this reason, the subject requires careful examination. Forest fire management can be viewed as getting the right amount of fire to the right place, at the right time, and at the right cost. This definition raises the question of finding the right balance between the beneficial and detrimental impacts of fire on people and forest ecosystems at a reasonable cost to society.

Fires are stochastic processes, which may be caused by humans or nature (e.g., lightning). Significant effort has been dedicated to building good forecasting models in order to anticipate the number of fires that will occur over certain time periods in a given space [14]. Fire prevention and fire detection are two important aspects of fire management. Some forest fire management agencies use fixed towers or lookout points to continuously scrutinize specific forest sectors; whereas, others use fire detection patrol aircraft. Designing such fire detection systems raises interesting OR challenges and questions. Also, once a fire has started, resources with air tankers and firefighters must be coordinated. Often, this must be coordinated for several simultaneous fires. Harvested areas can act as fire breaks that slow down the advance of fires. Hence, integration of fire management with harvest planning may be necessary to include fire aspects early in the planning process. Other examples of natural disruptions that may have a big impact are storms and pests.

Harvesting and Transportation

Harvesting includes the following main phases. The trees are cut and branches are

removed. The trees are then bucked (or cross-cut) into logs of specific dimensions and quality, which can be done in the harvest sectors or in lumber yards. The collection of logs and trees to roadside storage is called *forwarding*, and there are a number of different machines available. Trees, or logs, are then transported directly to mills or to terminals for intermediate storage. The forest residues are also used. They are converted into energy (e.g., wood chips) or chemicals. The harvesting is done by groups of harvest crews and the transportation is done by one or several transport companies.

Harvesting and transportation involve large costs and are often linked together. Figure 5 illustrates the main components of this part of the value chain. Several transportation modes including trucks (many different configurations) are combined with trains and ships. Tactical models are related to the selection and sequencing of stands, or cutting blocks, for harvesting in order to satisfy temporal demands for timber. In addition, road engineering is also a necessary component of tactical planning, since the industry is dependent on an efficient road network to provide access to harvest areas. Thus, the associated costs of road engineering and harvesting impact the viability of management plans. In the forest value chain, storage terminals (e.g., tree/log yards) are used for many reasons, including the benefit from the pulling effect and to protect against demand variation or changing weather conditions [15].

Tactical planning generally involves the use of mixed integer programming (MIP) to model decisions on the time and place of timber harvest, as well as the roads and terminals that should be built or maintained [16]. One important aspect is to get all data required to formulate models. For example, finding correct road investment cost involves many aspects, for example, distance to gravel supply, type of terrain, type of maintenance program, machines required, and so on. Another example is demand forecasting. The demand is a key driver in planning and the results are highly dependent on these values. Because these decision parameters typically vary, the use of robust and stochastic optimization is increasing.

Timber is typically defined by the length and diameter of the logs and by the quality of the wood. The lower part of the tree has a larger diameter, and thus a higher value, and is sent to high-end sawmills. The upper, thinnest part of the tree has a lower value, and is best suited for pulp and paper mills. It is not easy to match the available standing timber exactly to specific product orders. LP models have been particularly useful in this regard, significantly reducing the loss incurred when greater diameter logs are used for lower value purposes, such as pulp. Backhauling, which aims to combine allocations of timber in order to reduce unloaded distances, is often an important part of the models. Backhauling can also be modeled in LP models although the model size increases substantially.

Figure 5. Example of alternative transformative divergent processes. (a) A conceptual representation of tree bucking into logs and (b) sawing patterns transforming logs into lumber or boards.

In many cases, bucking decisions are integrated into the decisions made about the stands that have to be harvested. The number of possible bucking patterns is very high, given the many combinations of lengths and diameters. Bucking can be carried out at sawmills, where each tree is scanned and analyzed individually, or in the forest, by implementing optimizers directly into mechanized harvesters. Dynamic Programming and metaheuristics are the main algorithms proposed for such processes, and commercial codes have been developed and are now used by many forest firms. Freshness, wood quality, and detailed distribution of diameter and length are the aspects that affect log prices and demand.

Operational routing of trucks in forestry has some special properties as compared to standard vehicle routing problems. The basic problem is a pickup and delivery problem with time windows. Trucks typically have different configuration and home bases. In addition, the demand is given for several days; so several daily routes must be found. The available supply is often larger than the demand due to inventory policies, and it is important to balance close supply points with more distant to balance truck capacity. Other aspects are queueing issues and coordinated planning with loaders. Depending on the country and company, some aspects can be simplified and used in the development of solution methods. There are a number of methods developed ranging from simple heuristic and metaheuristics to exact methods. Many models are based on set partitioning type models. GIS are required to provide computations of both distances and time estimates.

PULP AND PAPER VALUE CHAINS

As the logs or chips are transported through the pulp and paper supply chain, they are transformed first into pulp and then into paper, which is then formed into commercial rolls or sheets. In pulp production, the fibers are mixed with chemicals according to a specific recipe to produce the different pulp grades. Recycled paper is often introduced to the pulp, which is then used to produce

jumbo reels of paper of a specific grade, finish, base weight, and color. The jumbo reels are cut into rolls, which can be either sold directly on the market or sheeted for printing and writing paper products. From the mills, the paper is distributed either directly or through a network of wholesalers, distributors, and merchants. Customers vary with the type of paper; for example, printers may buy newsprint; retailers may buy fine paper; and food chains may buy packaging materials. A typical pulp and paper company owns many mills. This pulp and paper supply chain uses all modes of transportation (e.g., trucks, trains, and ships) to transport logs or chips from the forest to the pulp mills; though pulp products may be transported by truck, they mostly travel by train or ship; finished paper is usually moved by train or truck.

It is only recently that the issues of supply chain design in the pulp and paper industry have attracted the attention of practitioners as well as researchers. This can be partially explained by the fact that the industry has typically been driven by a push model in which the main decisions are related to when and where to cut the trees, followed by decisions about processing and selling the resulting products.

The pulp and paper value chain often covers large areas and it is important to design the network. This is a strategic planning problem as mills have to be used for 20–30 years. On a shorter term, it is also important to decide about terminal or distribution center (DC) structure, use of transportation modes (e.g., a combination of vessel, train, barge, and truck), allocation of products to mills, and production capacity. In addition, there is also a need to consider national taxation legislation, transfer price regulations, environmental restrictions, trade tariffs, and exchange rates. The OR models used are often large-scale MIP models. Such model can also be integrated with harvesting or sourcing decisions [17].

Given a distribution network, there may be several customers and one problem is to determine the orders and the level that should be accepted. For example, one order could be profitable only if there is another customer in the same region so that the

same terminal can be used. Pulp and paper mills are often specialized for particular products; so, it is important to combine products—mills and market zones. Also, if vessels are used for long transports, it is important to find good routes and integration between the self-owned fleet with short-term spot vessels. Such models are often MIP models, and they are used to support analysis of what-if scenarios.

The mills can schedule production around campaigns where products are produced in cycles, one at a time, introducing switching costs. These costs can be related to a lower production speed or addition of chemicals needed to satisfy specifications on properties (e.g., brightness). In the pulp and paper industry, switch costs are known to be sequence dependent. This means that the costs of switching between two products are affected by the sequence in which the products are produced, which has in turn led to various scheduling formulations with inventory planning.

Roll cutting is a well-known problem that arises with paper machines. Such problems can often be solved using column generation. However, in an industrial setting, there are many practical issues to consider, such as a limited number of knives in the cutting machine, the width of the cutting machine, the products that must (or must not) be cut in the same pattern, different product due dates, or limited inventory space or replenishment opportunities. Another practical issue is that, given a minimum number of rolls, the objective is to use as few cutting patterns as possible in order to limit setup costs and times. These concerns result in many new constraints, and heuristic approaches to these problems have been suggested [18].

Optimal control is used in many process control applications. When several closed loops have to be controlled simultaneously, nonlinear model can be used to propose the overall control.

LUMBER, PANEL, AND ENGINEERED WOOD VALUE CHAINS

The lumber, panel, and engineered wood industries transform the logs into boards (to

produce lumber and dimension parts) or into flakes (to produce panels). Boards and panels are used as components for engineered wood products, which are mainly used in construction or decoration.

Lumber is produced in stages. First, the logs are sawn into boards in sawmills. In modern sawmills, scanners read the geometry of the logs and optimize the cutting in order to produce maximum value. To prevent production bottlenecks, a mix of logs is used in the sawing lines. The boards are then dried in dry kilns, either by batch or through a continuous process, and are grouped according to specific configurations in order to maximize the quality of the output. Finally, the boards are planed on finishing lines, where setup constraints affect the finishing process. The setup times are mainly due to the process of emptying the buckets containing the finished products.

Panels are produced from wood parts, flakes, or fibers, which are dried, glued, and pressed together. The wood flakes are obtained from logs that have been stored in ponds to soften, while the fiber is obtained by mechanically refining sawdust, shavings, or residues. The wood is then mixed with resin and spread to form a mattress, which is then cut to length. The final board is produced by pressing this mattress under heat conditions. When the panels are used to make engineered wood products (e.g., prefabricated wood I-beams), they are again cut into smaller dimensions to meet specifications.

Engineered wood products are typically produced by assembling lumber and panels. They are used for structural parts in residential and nonresidential constructions (e.g., flooring or roofing systems). Many standards regulate lumber, panel, and engineered wood products. For example, in North America, softwood lumber must conform to the NLGA (National Lumber Grade Authority, www.nlga.org) certification that defines the grades, or quality, for softwood lumber of certain dimensions, while hardwood lumber must conform to the NHLA (National Hardwood Lumber Association, www.nhla.com) grading rules.

Customers exhibit different buying practices, all of which are greatly affected by the variation of the spot market prices. These practices can be grouped into three different categories: spot market, vendor-managed inventory, and contract based. The vendor-managed inventory and contract-based approaches usually offer a financial advantage to the producer in exchange for guaranteed deliveries.

At sawmills, wood is normally sorted into different log types with specific properties. Typical sorting is based on diameter, length, and quality. The sorting can also take place at the harvest areas. However, creating more assortments for the sorted wood is costly and generally a single party cannot independently make the decision to create more assortments. The challenge is to make wood sourcing decisions, including wood sorting strategies as well as technology investments, in order to maximize the profit of the supply chain taking into account fiber sourcing possibilities, production, and market opportunities [19]. LP models can be used to formulate tactical models.

The transformation activities involve generic many-to-many processes; these processes consume a set of input products that are combined in different ways or cut according to different cutting patterns (e.g., bucking or sawing patterns) in order to produce a set of output products. When multiple products are produced through these processes, the products are individually classified as either coproducts or by-products. Coproducts are demand-driven products; by-products are the secondary results generated by the process—usually low-value products (e.g., bark or saw dust)—and are sold on side markets. In many circumstances, several alternative processes (e.g., cutting patterns) are available to achieve the desired transformation; under these circumstances, the planning decisions must also select the processes to be used. Figure 5 illustrates different processes found at sawmills.

Production planning at sawmills includes many decisions. One example is the decision on the type of cutting pattern to be applied to a specific log type; since the process is divergent, it is important to balance production

against demand while taking into account the cost of inventory. A second example is the decision on the type of drying process to be used for each of the green lumber products produced, which is a campaign-scheduling problem. Often there are capacity restrictions on some processes and hence products may be transported between mills in order to better use the capacities. Some models also integrate bucking decisions and production planning decisions at the mills, in order to buck the trees so the mills get the best logs for an optimized efficient production of the ordered lumber products. In such cases, there is a need to use column generation techniques to generate different supply possibilities [20].

To analyze the performance of lumber supply chains, some work is done to build agent-based simulation platforms [21]. This permits the modeling of all business units within the chain and simulates the impact of the combined planning behaviors.

At the operational level, the cutting problem is often critical. Whether dealing with hardwood or softwood lumber, panels or engineered wood products, optimal cutting of incoming products is challenging in terms of material yield management as well as demand satisfaction. The general literature provides many models that deal with cutting problems. In the wood products industry, difficulties stemming from wood defects and wood grading must be considered, raising the need to tackle difficult two-dimensional or even three-dimensional problems. In addition, the high production speed requires fast solvers. Most cutting solvers are based on dynamic programming or heuristics [22].

ENERGY VALUE CHAINS

The energy industry uses forest product residues to produce energy. Forest biomass is directly supplied from the forest or from the mills. This biomass, which serves as biofuel for producing energy, can be transported bulk, bundled, or chipped. The raw materials are often branches, tops, stubs, and low-grade logs that are converted into wood chips. Chipping can be done in the forest, at the intermediate storage terminals

or at the heating plants. Depending on the location, different systems for chipping and transportation are used. Transportation constitutes a large proportion of the overall handling costs, and there is obviously a trade-off between chipping directly in the harvest areas or waiting to chip at the terminals. It is typically cheaper to chip at terminals, but transporting non-chipped forest residue is more expensive than transporting wood chips. The demand for wood chips is correlated to the weather and is as such uncertain. Often LP-based models with transportation, production, and inventory decisions are used [23]. Owing to uncertain demand, robust models are being developed and used [24].

Some chemical processes can be used to transform the residues into specific biofuels (such as ethanol). The energy supplied can be used to satisfy public needs (e.g., heating plants that supply residential and industrial sectors with hot water for heating) or industrial needs (e.g., drying kilns). As the cost of fuel rises, using wood residues for energy becomes an increasingly attractive alternative.

DISCUSSION

Integration and Methods

Although value chain planning has helped to improve the performance of many companies, the challenge of integrating the different planning problems from the forest to the market still remains [25,26]. This is the case when the procurement, production, distribution, and sales activities need to be synchronized throughout a set of independent business units (e.g., entrepreneurs, carriers, sawmills, and pulp and paper mills), their suppliers and their customers. Forest product value chains are generally composed of many interconnected business units that are constrained by their divergent processes. For example, one supply chain can include the producers who manage a mix of species in the forest, the various entrepreneurs who convert these trees into logs or chips, the sawmills that cut the logs into boards or dimension parts, and the pulp and paper

mills that use the wood chips to create reels of paper that are then cut into smaller product rolls or sheets. These varied many-to-many processes make the task of integrating the procurement, production, distribution, and sales activities very complex, given that these activities are always bounded by the trade-offs between yield, logistical costs, and service levels. The consequence of this is that although the number of products in the first stage is low, in the later stages it increases often to several thousands of end products.

In addition to integrating the varied activities, it is also crucial for value chain planning to integrate strategic, tactical, and operational decision making. Because of the size of the problems, due to the number of products, processes, suppliers, customers, and time periods, decomposition techniques and/or hierarchical planning approaches are typically needed. Strategic decisions impose constraints on the tactical planning process, and the ensuing tactical decisions impose constraints on the operational planning process. Many OR models and methods have been proposed to support planning problems in the forest products industry [1–5]. Because the planning horizon ranges from very short (parts of minutes) to very long (several hundred years) time periods, there are very different requirements of the solution time (Fig. 6). For this reason, heuristics, metaheuristics, and easy-to-solve network methods are generally used for operational problems, whereas MIP and stochastic programming methods are better for tactical and strategic planning problems. Many of the OR models are implemented in diverse industrial decision support systems (DSS), which are often integrated into application-specific databases holding all the information needed for the models and the GIS that are used to visualize the input data and results.

Collaboration

There are often many actors in the forest industry, which provides good opportunities for collaboration. This has been explored in the context of transporting logs to mills [27]. Often, many companies operate in different

Figure 6. Illustration of required solution times with respect to planning period. [Source: revised from [1].]

parts of the country, which provides opportunities for optimizing backhauling operations. This opportunity has been addressed in different parts of the world, using the specific wood allocation and trucking constraints found in each region. Models based on game theory have been used to propose a fair allocation of both revenues and costs. Another example is that many companies obtain their wood allocations from unevenly aged forests owned by the government; they often need to agree on a common in-forest harvesting plan. This problem can be addressed by proposing collaborative approaches to help the negotiation process converge on a profitable balanced solution. Studies on the relationship between paper mills and customers have also been carried out. Different approaches to integration can be simulated and optimized, starting with the traditional make-to-order, and then moving toward continuous replenishment, vendor-managed inventory (VMI), and collaborative planning forecasting and replenishment (CPFR) [28].

Future Challenges

The OR challenges in the forest industry are similar to many other areas. Integrating different parts of the supply chains still provides many challenges. The size of the problems becomes large and complex. Methods that are able to solve the problems in short times but with high-quality solutions must be developed. In many applications, there is uncertainty in the data. This is true for measured data, for example, supply information in forest areas as well as forecasts for future demand. Although better methods can increase the quality, stochastic and robust optimization will be more important in the future. To develop a useful DSS for planners, it is important to integrate GIS with the OR models and methods. Also, many planners have no OR background and it is critical to educate these persons regarding the proper use of OR tools.

Ohio

Optimization is a branch of operations research that deals with optimal performance in the face of constraints. The optimizer's goal is to find the best way to perform a difficult task. Usually, the task is difficult because of the constraints that accompany/define it. In this article, we show that visual art, a field that may seem—at least initially—to have no use for optimization whatsoever, is actually a very natural area of application, filled with opportunities for both optimization and optimizers.

The reason why is simple: Artists, like everyone else, face constraints. They must work within budgets. They must meet deadlines. If they enter competitions or juried shows, they must make sure that their pieces satisfy the rules of entry. If they take commissions, they must (or at least should) follow their clients' instructions. And no matter what media they choose to work with, they must deal with the particular constraints—imposed by the laws of physics—that govern how those media work. (Painting with watercolors is different from painting with oils, and painting on rice paper is different from painting on canvas.)

Given that artists are creative, one might think that if it were up to them, they would do away with constraints. After all, constraints *constrain*. They restrict. They limit one's choices. It would seem that constraints inhibit creativity.

But actually, there is much evidence to the contrary. Many artists embrace constraints.

Some need deadlines to be able to finish their work, and some believe that when their choices are limited, they are much more focused and creative:

When forced to work within a strict framework, the imagination is taxed to its utmost and will produce its richest ideas.

T.S. Eliot

Creativity arises out of the tension between spontaneity and limitations, the latter (like the river banks) forcing the spontaneity into the various forms which are essential to the work of art or poem.

Rollo May [1]

A large part of the beauty of a picture arises from the struggle which an artist wages with his limited medium.

Henri Matisse [2]

In fact, many artists go so far as to impose artificial constraints upon themselves. Consider George-Pierre Seurat. When viewing his painting *A Sunday on La Grande Jatte* (1884) from up close, one sees a mass of colorful dots. Upon backing away from it, one's eyes fuse the dots into an image of a group of Parisians relaxing on an island on the Seine. To create this masterpiece, Seurat set himself the task of producing the best possible depiction of what he saw on the riverbank, subject to two highly restrictive, manufactured constraints: he had to keep his colors separate, and he could only apply paint to the canvas with tiny, precise, dot-like brush strokes. Seurat's self-imposed constraints gave rise to a spectacular piece of art, the most widely reproduced example of what art historians call *pointillism*.

When the computer is considered as an artistic medium, the problem of satisfying constraints—formerly a purely cognitive process—becomes a practical opportunity for the application of optimization algorithms. If the constraints can be articulated in a form that the computer can understand, and a domain established within which a satisfactory artwork might be found, then an optimization algorithm can be made to search through the domain for a bestpossible solu-

tion. That solution can then be synthesized on the computer screen or used as a template for constructing an artwork by hand.

In the rest of this article, we explore applications of optimization algorithms to the computer-based synthesis of art. We highlight a few of the most indicative examples (rather than attempting to offer a comprehensive survey) and outline the strategies and algorithms used by those examples. We have chosen to break down our presentation broadly into three topics: tile-based methods, freeform arrangement of elements, and line art.

LAYING TILES

The predominant means of representing photographs or other pictorial information digitally is as a raster image. A raster image (or, more succinctly, an image) can be thought of as a function I that maps pixel locations (x,y) to some color space. Here, x and y are positive integers in the ranges $\{1, 2, \dots, W\}$ and $\{1, 2, \dots, H\}$, respectively, for width W and height H . The range of I might be monochromatic luminance values in the interval $[0, 1]$ (where 0 represents black and 1 represents white), colors represented by RGB triples in $[0, 1]^3$, or values in some other space. These pixels need not be restricted to individual color samples. For example, given an RGB source image I of size $W \times H$, we may wish to group pixels in I into $k \times k$ blocks. The result is a new image I' of size $\frac{W}{k} \times \frac{H}{k}$, in which each “pixel” is a tuple of size $3k^2$ holding all the RGB information from a $k \times k$ block of pixels in I .

Once a photograph is seen as divided into a grid of pixels (or blocks of pixels), it is natural to seek an artistic or playful rendition of that photograph in which each pixel is replaced by some novel object or picture. Every time an artist decides to construct a mosaic out of some new material, a new self-imposed constraint is born, giving rise to a new form of artistic expression. The pixels take on a life and identity of their own. The viewer’s eye is left in a dynamic tension between the image as a whole and the small elements that make it up. These elements

can complement or comment on the image of which they are a part.

Renowned photorealist painter Chuck Close has spent most of his career working in this medium. He typically divides a photographic portrait into a grid, and then approximates the average color of each grid cell in paint (using, for example, concentric rings of multicolored paint). Computer graphics pioneer Ken Knowlton has also created works that emphasize the interplay between an image and the elements used to represent it [3,4]. In many of his works, small objects are arranged in a regular grid, with the size or color of the element chosen to approximate the tone of an underlying image. Fragments of a broken teapot reassemble into an image of a teapot; portraits are formed from hundreds of tiny seashells. In one famous image (which we will soon revisit), a portrait of Martin Gardner is created from six sets of double-nine dominoes. More generally, mosaicists have used dice [3], dominoes [3–8], Lego[®], bricks [9], toy cars [3], spools of thread [4,10], baseball cards [4,11], and food [12].

As computers became capable of handling more (and larger) images, artists and computer scientists began to experiment with using images themselves as elements to compose larger images. In a “photographic mosaic,” blocks of pixels in a target image are approximated using tile images taken from a database [11,13,14]. The goal might simply be to minimize color differences between blocks and tiles, or to find tile images with structures that align with visual features in the blocks. Today, photographic mosaics are commonplace and many software tools exist that allow hobbyists to create their own. Photomosaics typically take advantage of an individual’s photograph collection or of the vast availability of digital photographs on-line; alternatively, frames of video can provide an abundant source of tiles [15].

When working in the realm of mosaics, some artists are compelled to go beyond the inherent constraints of their materials. The domino mosaics of Knowlton, Knuth, and Bosch are not only made out of dominoes but also made out of complete sets of dominoes. (Bosch’s 44-set mosaic of President

Obama contains exactly 44 dominoes of each type—exactly 44 double-blank dominoes, exactly 44 zero-one dominoes, etc.) Ken Knowlton’s portrait of Helen Keller is composed of the 64 characters of the Braille writing system, each appearing 16 times. Related constraints have also been applied in the construction of photographic mosaics. Chris Jordan’s *Denali/Denial* mosaic arranges 24,000 (digitally altered) logos from the GMC Yukon Denali sports utility vehicle (representing six weeks of sales in 2004) into an image of Denali (also known as Mount McKinley). A Robert Silvers photomosaic, commissioned by *Playboy* for its 45th anniversary, renders the centerfold of the magazine’s first issue as a photomosaic of the first $45 \cdot 12 = 540$ of its covers.

When approximating image pixels by objects taken from some inventory, the simplest case is to choose a best possible object independently for each pixel. (We might also imagine that our inventory consists of an unlimited supply of every possible object.) In this case, very little optimization is necessary; we can simply choose the best-fit object independently for every pixel. Consider the simple case of monominoes, black squares printed with zero to nine dots, arranged in the patterns found on double-nine dominoes. Each of those monominoes can be seen as approximating one of ten fixed luminance levels spread evenly between black and white. For each block of square pixels in a target image, we quantize its luminance to one of those ten values and place the corresponding monomino. This algorithm is analogous to ordered dithering techniques in computer graphics [16].

The need for optimization becomes more apparent when blocks must be approximated by tiles taken from a finite inventory. In a Knowlton-style mosaic, we might have a fixed supply of shells or teapot shards, and wish to find the most successful overall arrangement of those pieces that approximate the source image. Or, we might have a database of tile photographs to use in a photographic mosaic, but we wish each photograph to be used at most a small number of times. In such cases, a greedy choice in one part of the image will affect the availability of a good approximation

elsewhere; a successful image will achieve a globally optimal approximation.

Let I be a $W \times H$ image, and suppose we have an inventory of tiles $T = \{T_1, \dots, T_n\}$. (We may think of each tile as a small image of the same size and shape as the pixels in I .) In order to evaluate the quality of the approximation, we are given a distance function $\delta(C, T)$, where C is a color in the same space as the range of I and T is a tile. This function measures how effectively the given tile approximates a pixel in the source image; we assume that $\delta(C, T) \geq 0$ and that smaller values denote better approximations. The goal is to define a mapping $f(x, y)$ that chooses, for each pixel location (x, y) , a particular tile T_j in such a way that no tile is used more than once (if we wish to allow duplicates, we can preload them into the inventory). Of all such mappings, we seek the one that minimizes $\sum_{x,y} \delta(I(x, y), f(x, y))$, the total amount by which the tiles approximate the original image.

Problems of this type can be efficiently solved by constructing a complete, weighted bipartite graph, in which each pixel location (x, y) is connected to every tile T_j by an edge of weight $\delta(I(x, y), T_j)$, and computing the minimum-weight matching that uses all of the pixels. Analogously, they can be seen as instances of the assignment problem.

Our task becomes much more complex when tiles do not match up one to one with image pixels. Consider Knowlton’s domino portrait of Martin Gardner, mentioned above. Each tile is a domino that must serve as an effective approximation of two adjacent pixels. However, any given pairing of numbers occurs only once per set of dominoes, and so a desired pairing might be in short supply. Moreover, dominoes may be oriented horizontally or vertically, and we must contend with the superexponential number of ways to cover pixels in a rectangular image with dominoes.

In this case, a simple technique like bipartite matching is no longer rich enough to encode the space from which a successful solution will be found. However, the construction of domino art can be reduced in a natural way to an integer programming problem [5].

Let D_n represent the set of double- n dominoes. This set can be thought of as consisting of the $\binom{n+2}{2}$ distinct ordered pairs $d = (d_1, d_2)$ for integers $0 \leq d_1 \leq d_2 \leq n$. Now let us suppose that we are given an image I of size $W \times H$, and s sets of double- n dominoes to cover it with (whence $WH = 2s\binom{n+2}{2}$). We define a set P consisting of all pairs of adjacent pixel locations:

$$P = \{(x, y), (x+1, y)\} | 1 \leq x < W, 1 \leq y \leq H\} \cup \\ \{(x, y), (x, y+1)\} | 1 \leq x \leq W, 1 \leq y < H\}.$$

Any pair in P can potentially be covered by any domino. Furthermore, because the domino can be rotated by 180° when covering the pair, its two halves can be assigned to the pair's pixels in two possible ways. Let $p = \{(x_1, y_1), (x_2, y_2)\}$ be a pair, $d = (d_1, d_2)$ be a domino, and δ be a distance function that compares individual pixels to domino halves. We define a new distance function δ' that compares dominoes to pixel pairs, taking into account their two possible orientations:

$$\delta'(p, d) = \min(\delta(I(x_1, y_1), d_1) + \delta(I(x_2, y_2), d_2), \\ \delta(I(x_1, y_1), d_2) + \delta(I(x_2, y_2), d_1)).$$

We now formulate an integer programming problem as follows. We define a set of variables x_{dp} , where d ranges over all dominoes in D_n and p ranges over all pairs in P . The intention is that $x_{dp} = 1$ if and only if domino d is used to cover pair p ; otherwise $x_{dp} = 0$. With these variables in mind, we wish to minimize

$$\sum_{d \in D} \sum_{p \in P} x_{dp} \delta'(p, d),$$

subject to the following constraints:

$$x_{dp} = 0 \text{ or } 1 \text{ for all } d \in D \\ \text{and all } p \in P \quad (1)$$

$$\sum_{p \in P} x_{dp} = s \text{ for all } d \in D \quad (2)$$

$$\sum_{d \in D} \sum_{\substack{p \in P; \\ p \ni (x, y)}} x_{dp} = 1 \text{ for all } 1 \leq x \leq W \\ \text{and all } 1 \leq y \leq H. \quad (3)$$

The first set of equations above forces the variables x_{dp} to decide whether or not to place a domino atop a given pair. The equations in the second set require that each distinct domino be used exactly s times. The third set prevents dominoes from overlapping by asking that every pixel location is covered by precisely one domino.

The tangled interactions between variables introduced by the third set of equations complicate the domino portrait problem, to the point where it can no longer be seen as a simple instance of the assignment problem. Still, the problem instances that arise in the creation of a domino artwork have been found to be tractable in practice [6]. An example of a domino portrait is given in Fig. 1. (Knowlton's original domino portraits relied on a two-phase algorithm in which the image was first partitioned, once and for all, into pairs of adjacent squares, and then dominoes were placed into these domino locations. Knuth later showed that each of these phases could be modeled as an instance of the assignment problem [8].)

Having developed this integer programming framework for tile-based image approximation, it becomes possible to explore variations that depend on other constraints between tiles. For example, Bosch and Pike considered methods for approximating every image pixel with a gray square chosen from a small set of tones [17]. They impose the constraint that neighboring pixels receive contrasting tones, producing images they call *map-colored mosaics*. They achieve this goal with a similar objective function as above, with the addition of equations that prevent adjacent pixels from receiving the same tone. In other work, Bosch uses tiles that must seamlessly match across their boundaries with neighboring tiles [18]. Again, the compatibility of adjacent tiles can be expressed as constraints in an integer programming problem.

FREEFORM ARRANGEMENT OF PRIMITIVES

The previous section explored cases in which elements (colored squares, photographs, dominoes, or other tiles) could be placed in a discrete, finite set of configurations. Optimization has also successfully been used to create freeform artistic compositions, in which elements can be positioned arbitrarily in the image plane and possibly even deformed. Typically, such techniques use a continuous optimization process to find an optimal or near-optimal arrangement, though even the simple geometric optimality of Voronoi diagrams has been used for decades to create abstract compositions [19].

As discussed in the introduction, there is a natural analogy to be drawn with abstraction in many styles of art. Any artistic medium or technique imposes constraints on the artist's range of expression. The artist must then seek to create the best possible reproduction of a scene subject to those constraints. Even in a highly expressive medium such as oil paint and canvas, we might imagine that the artist would at least seek to minimize the amount of paint used.

For example, suppose we are given a color image $I(x,y)$, which we wish to approximate via a painting P . The painting consists of an ordered sequence of strokes, each of which is defined by a curved path in the image plane, a thickness, and a color. Any such painting can easily be rendered to yield a color image, and the resulting image can be compared to I as a measure of the quality of P .

Hertzmann uses this sort of stroke-based model to construct painted approximations of images via a relaxation process [20]. He articulates several ways that we may wish to measure the quality of a painting. Obviously, the similarity of the painting to the original image is one crucial measure; Hertzmann weights this measurement by a spatially varying scaling factor, allowing unimportant parts of the canvas to be painted more roughly. Other measures are the total surface area of all paint strokes, the number of strokes, and the surface area of the uncovered part of the canvas. A user of this algorithm may wish to vary the relative importance of these measurements. Hertzmann's overall objective function is a weighted sum of these individual terms; the user can adjust the

Figure 1. An example of a domino artwork: a portrait of Venus from Botticelli's "The Birth of Venus," constructed from precisely nine complete sets of double-nine dominoes.

Figure 2. Four sample paintings of a photograph of the Queen Mary, created using Hertzmann's paint by relaxation algorithm [20]. By varying the texture and transparency of strokes, together with the weights used in the objective function, different visual effects can be achieved. [Source: Images courtesy of Aaron Hertzmann, based on a photograph by Philip Greenspun (<http://philip.greenspun.com/>).]

painting style by varying the weights. The idea of constructing an objective function from a weighted sum of competing terms, and then putting the weights in the hands of the user, recurs frequently in the application of optimization algorithms to the creation of art in computer graphics.

Hertzmann's algorithm iteratively proposes perturbations to the current state of the painting, and accepts those perturbations if they reduce the value of the objective function. He defines a set of possible perturbations, including the addition, removal, deformation, and recoloring of strokes. Four sample paintings created using Hertzmann's algorithm are shown in Fig. 2.

Related approaches use genetic algorithms (GA) or genetic programming (GP) to construct an approximation of an image [21]. These approaches typically begin with a fixed set of strokes (for example, oriented line segments) and use an evolutionary computation to find optimal positions and orientations for those strokes. Here, the objective function is based entirely on the similarity of the drawing to the original image; Hertzmann's terms for number of strokes and total stroke surface area are implicit in the construction of the problem instance. A related approach, pioneered by Collomosse and Hall, distributes stroke locations based on a measure of perceptual salience [22]. Their algorithm performs a genetic crossover of two paintings

by preserving the strokes from each that contribute most toward the reproduction of the source image.

A hybrid between tile-based methods and freeform element placement can be found in the so-called *packing* algorithms. These techniques introduce additional constraints on spacing between elements; for example, we may wish to prevent elements from overlapping. One simple application is stippling, in which black discs are distributed across the image plane so that their varying radii and spacing approximate the darkness of a source image I . Most stippling algorithms are approximate forms of importance sampling, where samples are placed more densely in darker parts of an image. A practical stippling technique is weighted Voronoi stippling, a weighted version of Lloyd's method (an iterative algorithm for constructing a centroidal Voronoi diagram) that relaxes sample points into a stippled drawing of an image [23].

In many packing algorithms the goal is not to approximate continuous tone or color, but to fill a set of container regions as tightly as possible while controlling gaps and overlaps. For example, In Jigsaw image mosaics, each container region is filled using an iterative algorithm with backtracking that distributes elements inward from the container's outer

boundary [24]. The placement of tiles is evaluated based on a weighted sum of color reproduction, overlaps, gaps, and tile deformation.

In an alternative approach to stylized illustration, artistic thresholding begins with a subdivision of the image plane into disjoint regions derived from segmentation [25]. An optimization process then colors each of the regions black or white, resulting in a stylized monochromatic illustration with no depiction of tone. As with Hertzmann's algorithm, the quality of a given assignment is computed as a weighted sum of several terms. The two most important terms allow the user to trade off between the overall approximation of tones in the source image and the representation of high-contrast edges between adjacent segments.

LINE ART

Recently, some research in artistic optimization has explored the use of continuous line drawing to represent images and designs. The basic idea is simple: approximate the tone of an image via a simple closed path. The path will necessarily take a twisty, meandering route as it distributes its tone over the entire image plane. Contemporary visual artist and designer Mo Morales [26] has created similar artworks by hand.

TSP Art creates continuous line drawings using the traveling salesman problem, one of the cornerstones of optimization research [27]. In a first phase, cities (points) are distributed over the image plane so that their density approximates the tone of a given image. Weighted Voronoi stippling provides an excellent point distribution technique for this purpose, though it is also possible to use an approach such as point repulsion to achieve an even distribution [28]. Once cities are placed, they are joined into a simple closed path using a heuristic TSP solver such as the Lin–Kernighan approach provided by Concorde [29]. An example TSP portrait is shown in Fig. 3. We do not expect this solution to be optimal, but the heuristic will produce a single closed path with no self-intersections. The polygon corresponding to the tour can serve as the final drawing, or it can be further

modified for aesthetic purposes (for instance, its thickness can be modulated to improve tone reproduction or it can be smoothed into a curve). A set of city distributions used in the creation of TSP Art was recently offered as large-scale challenge problems for the TSP [30]. Because of the evenness of the spacing between cities, we can expect these problem instances to feature a broad range of near-optimal solutions, making the true optimum especially difficult to find.

Similar results have also been achieved using a geometric attraction-repulsion model inspired by reaction-diffusion systems [31]. In this approach, a physical simulation allows points in a closed path to exert forces on each other. The force model, based on the Lennard-Jones potential in chemistry, induces a strong repulsive force on points that are too close together and a mild attractive force on distant points. The “rest distance” varies spatially with image tone. Further steps in the simulation add and remove points as needed and filter the curve for smoothness. Beginning with a simple shape such as a circle, this technique will gradually evolve coral-like meandering curves that capture the tone of images.

The tour produced by the Concorde TSP solver will not intersect itself, but beyond that it is difficult to control what kind of tour is created. Recent research has considered ways that the tour can be “steered” to satisfy visual goals [28]. In particular, it would be valuable to be able to specify that certain regions in the image plane were definitely inside or outside of the tour path, or that two regions were on the same side. While TSP solvers like Concorde cannot encode such side constraints, they can easily be added as equations to the Dantzig–Fulkerson–Johnson integer programming formulation of the TSP.

CONCLUSION

This article has offered a glimpse of some of the ways that optimization has been used as a tool in the visual arts. We have encountered some of the more popular styles of art that have been explored via optimization

Figure 3. An example of TSP Art: the face of Leonardo's "Mona Lisa", rendered from a single, continuous closed curve.

(tile-based designs, paint strokes, and line art) and some of the optimization techniques that have figured into those explorations (the assignment problem, integer programming, continuous energy minimization, etc.).

When optimization is used to create visual art, it is alluring to envision an accurate model of human aesthetic response as the ultimate objective function. The constraints in which a human artist works could then be seen as delineating a search space, in which we seek an image that maximizes this idealized aesthetic response.

Of course, such an objective function is impossible, or at least well beyond our computational capabilities and our understanding of human perception. There is a great gulf between this ultimate view of artistic optimization and the simple mathematical objective functions we use in practice. In that gulf, we see endless opportunities for future applications of optimization in visual art.

Each new optimization offers another point of view from which to understand the way we see art, and another source of beautiful images.

INTRODUCTION

In 2008, approximately 1,437,180 Americans were diagnosed with cancer and 565,650 died from it: more than 1500 people a day, making cancer the second leading cause of death in the United States [1]. American men have slightly less than a 1 in 2 lifetime risk of developing cancer; for American women, the risk is a little more than 1 in 3 [1]. Table 1 presents the estimated number of new cases and deaths by selected cancer types in 2008. Figure 1 shows how the incidence and mortality rates of cancer change over time. The economic impact of cancer is also huge. According to the National Institutes of Health, the total cost of cancer care in the United States in 2007 was \$219.2 billion, where direct medical costs accounted for \$89 billion [1].

Although cancer is a highly fatal disease, as a result of advanced treatment options, most cancers are now curable if detected early. For instance, Surveillance Epidemiology and End Results (SEER) program reports that five-year survival rates for localized (an early stage) and distant (an advanced stage) breast cancer patients are 98% and 23%, respectively [2]. Obviously, a successful screening program would improve the effectiveness of cancer treatment. The five-year relative survival rate for all cancers has improved from 50% in 1975–1977 to 66% in 1996–2003 [1], which can be attributed to the

progress in both diagnosing certain cancers at an earlier stage and improvements in treatment the progress [3]. Table 2 lists screening modalities for selected cancer types.

Although screening of a population of asymptomatic individuals can diagnose some early-stage cancers, the vast majority of these individuals receive no benefit since cancer deaths are prevented in only a small fraction of the screened population [5]. In fact, the screened population may be exposed to additional health risks and even death (e.g., perforation during a colonoscopy screening) as a result of screening, such as complications from the screening procedure, from false-positive test results that trigger unnecessary invasive follow-up procedures (e.g., breast biopsy after mammography), and from misdiagnosis and overtreatment of cancers that would have never caused death [5]. Furthermore, population screening is very expensive. Burnside *et al.* [6] estimate that the total costs of just mammography screening for breast cancer and associated work-up of positive findings were between \$3–5 billion in 2001. Screening asymptomatic individuals therefore requires a careful analysis of the benefits and risks of screening in both utilitarian and economic terms.

The complexity of selecting a cost-effective cancer screening program creates many challenges that can be addressed using a variety of operations research (OR) tools. There are several review articles that summarize statistical and OR applications in cancer screening. Heidenberger [7] reviews the studies using quantitative approaches that focus on determining which screening strategy should be used for a population or an individual. Stevenson [8] summarizes statistical models considering the problem of planning and evaluation of cancer screening, whereas Pierskalla and Brailer [9] summarize mathematical models for cancer screening including the earliest OR applications. Knudsen *et al.* [5] provide a comprehensive summary of articles that use simulation methodology, the most

Table 1. Estimated New Cancer Cases and Deaths in the US in 2008 for Selected Cancer Types [1]

Cancer Type	Estimated New Cases	Estimated Deaths
Lung cancer	215,020	161,840
Prostate cancer	186,320	28,660
Breast cancer	184,450	40,930
Colorectal cancer	148,810	49,960
Bladder cancer	68,810	14,100
Skin cancer	67,720	11,200
Leukemia	44,270	21,710
Pancreas cancer	37,680	34,290
Gastric cancer	21,500	10,880
Other cancers	462,600	192,080
Total	1,437,180	565,650

commonly used OR tool in cancer screening. Among all modeling (particularly simulation) studies, research by the Cancer Intervention and Surveillance Modeling Network (CISNET), a consortium of National Cancer Institute (NCI)-sponsored investigators, is noteworthy. CISNET investigators use simulation/statistical modeling and common inputs to assess the impact of interventions (e.g., screening and treatment) on current population trends in cancer incidence and mortality. More information about CISNET models is available elsewhere [3,10–12].

This article provides a review of the OR studies considering cancer screening that are either briefly described or not mentioned in previous review articles. We classify relevant literature by cancer type. We start with summarizing cancer screening studies that

Figure 1. Cancer incidence and mortality rates in the United States between 1975–2006 [2]. Cancer incidence^a data come from SEER based on nine sites (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, and Atlanta) whereas cancer mortality^b data come from US Mortality Files, National Center for Health Statistics, Centers for Disease Control and Prevention. Both rates are per 100,000 and are age-adjusted to the 2000 US population.

are not applied to any specific cancer type. We then describe OR models on screening for breast cancer, colorectal cancer, cervical cancer, and other cancer types. We present a list of the articles described in this study in Table 3. Finally, we briefly summarize some issues for future research in cancer screening.

GENERAL MODELS FOR CANCER SCREENING

This section describes general (mostly theoretical) studies that are not applied to any

Table 2. Screening Modalities for Selected Cancer Types [4]

Cancer Type	Screening Modalities
Breast cancer	Clinical breast examination, X-ray mammography, magnetic resonance imaging (MRI), ultrasound computed tomography (CT)
Colorectal cancer	Colonoscopy, fecal occult blood test (FOBT), sigmoidoscopy, virtual colonoscopy, digital rectal examination
Prostate cancer	Digital rectal examination, prostate specific antigen (PSA) blood test
Lung cancer	Chest X-ray, computed tomography (CT) scan
Cervical cancer	Pap smear test, HPV test
Bladder cancer	Microscopic urinalysis, urine dipstick, urine cytology, bladder tumor antigen (BTA), nuclear matrix protein (NMP22) immunoassay
Ovarian cancer	Cancer antigen 125 (CA-125) test, pelvic examination, transvaginal ultrasound

specific cancer type. In two related articles, Prorok [13,14] introduces a stochastic stationary point process that represents the natural history of a chronic disease such as cancer, under a given screening program. Prorok's stochastic model includes three states: disease-free, preclinical, and clinical states, where the sojourn time for each state is a random variable. The author defines the number of screenings as an exogenous variable to the model. The author also assumes that the time horizon is divided into equal-sized intervals and each screening is assumed to occur in one of these intervals. Prorok provides explicit formulations for the mean lead time, mean forward recurrence time, and proportion of detected cancers by screening for this model. The author performs a numerical analysis using hypothetical parameters.

Butler [15] provides a four-state discrete-time Markov process model to determine

the optimal inspection schedule for a system where the inspection itself may cause the failure of the system (e.g., X-ray screening to detect cancer). The author provides an explicit formulation for the inspection schedule that maximizes the expected lifetime of the system and shows in which cases it is optimal not to screen, always to screen, and to screen periodically. The author does not perform any computational analysis.

Lee and Pierskalla [16] develop a general stochastic model that can be used to make a cost-benefit analysis of population screening programs for contagious and noncontagious diseases. The objective of this model is to minimize the aggregate detection delay (or equivalently, minimize the average number of people who have the disease) subject to a budget constraint. The authors convert this stochastic model to a knapsack problem and solve it optimally. They consider both

perfect and imperfect tests, but assume constant screening test accuracy over time. They further assume that the number of susceptible people in the population is constant and the incidence rate is time-stationary. They account for noncompliance to recommended policies. They show that when tests are perfect (i.e., sensitivity and specificity of the tests are 100%), optimal screening policy consists of equally spaced screening intervals.

Milioni and Pliska [17] present a stochastic model to find the optimal inspection schedule for a deteriorating system progressing toward a failure, where the deterioration process is modeled as a continuous-time semi-Markov process. They consider two objectives: minimizing the inspection cost subject to the constraint that the probability of failure is less than a specified value and minimizing the failure probability while the total number of screenings is fixed. They note that their model can be applied to the cancer screening problem. They provide dynamic-programming-based methods to solve the optimal inspection scheduling problem for both objectives.

Houshyar [18] presents a general stochastic model formulation to derive the optimal screening policy for a given disease and population. The objective is to minimize the total cost of a screening program including the costs of screening tests, treatment, and death. The author classifies disease states as occult, clinically surfaced or detected by examination, cured, and death. The author assumes that the screened population is closed and death from cancer is independent of death from other causes. The author concludes that the optimal screening strategy is typically aperiodic and the screening interval is age-dependent.

Hanin *et al.* [19] provide a stochastic model that represents cancer recurrence under a specific screening schedule (or no screening) to evaluate the performance of cancer surveillance programs. They measure the performance of a given screening program by the difference between the expected tumor size with and without screening. They break the tumor progression into three stages: formation of initiated cells, transition from initiated cells to malignant clonogenic cells (cells

that have the ability to proliferate to regenerate the tumor), and transition from malignant clonogenic cells to a malignant tumor. They model time in each stage as a random variable and provide examples from different distributions. They present an explicit formulation for screening efficiency and derive the structural properties for an optimal screening schedule. They also present numerical results with hypothetical data. They find that a fixed number of screenings should be uniformly distributed over the decision horizon under exponential tumor growth.

MODELS FOR BREAST CANCER SCREENING

Breast cancer is probably the most commonly studied cancer type in the OR literature. There are several early studies on breast cancer screening such as Zelen and Feinleib [54], Kirch and Klein [55], Blumenson [56], Shwartz [57], Eddy [58], Voelker and Pierskalla [59], van Oortmarssen *et al.* [60], Houshyar and Al-Khayyal [61], which are described in the previous survey articles in detail.

Özekici and Pliska [20] develop an infinite-horizon, undiscounted, delayed Markov decision process (MDP) model that minimizes the total expected cost of inspection, false-positives, corrective actions (treatments), and failures such as deaths. They refer to this model as a delayed MDP because the sojourn time in healthy state is a general nonnegative random variable but once the process leaves healthy states, it behaves like a Markov process. They assume the disease aggression and test accuracies are stationary. They use breast cancer screening problem as an example and show that the optimal policy is not to inspect a person for whom the cost of failure is under \$55,000, where the cost of failure is defined as the sum of terminal medical care costs and a dollar value assigned to the possible loss of life.

Parmigiani [21] addresses the question of which age groups and what part of population to screen for breast cancer. The author utilizes a continuous-time non-Markovian stochastic model for disease progression and calculates the optimal policy that minimizes expected losses including financial costs,

side effects, wasted time, stress due to false-negative test results, mortality, morbidity, and cost of treatment. The author presents a set of sufficiency conditions which ensure that screening frequency increases with age. In another paper [22], Parmigiani finds an exact solution to this model when there are only two disease states and the test is imperfect. In a related paper, Parmigiani [23] studies the question of whether to screen or not, given the age and risk factors of the patient and whether to re-examine a recently screened patient.

Zelen [24] develops a continuous-time stochastic model to find the optimal screening policy such that the objective is to maximize a general weighted utility function. The author considers age-specific incidence while keeping all other parameters stationary. The author concludes that if the incidence is stationary and the sensitivity of the test is perfect, then the screening intervals should be equally spaced. As a result, the author suggests that women over 50 should have an annual mammography screening.

In a series of papers, Lee and Zelen [25–27] and Lee *et al.* [28] extend the model of Zelen [24] to address various problems in cancer screening such as the optimal time to initiate screening. Lee and Zelen [25] consider the problem of finding the best periodic screening schedule for the early detection of a given disease. They develop a three-state stochastic model based on the model of Zelen [24] and determine the best screening schedule using two approaches. The first approach imposes a limit to the probability of being in a preclinical state whereas the second approach maximizes the ratio of expected number of patients diagnosed by the screening test over the expected number of cancer patients. They assume patients have different disease development risks and the time in preclinical state is exponentially distributed. They then illustrate the performance of their proposed screening schedules on breast cancer. In a related paper, Lee and Zelen [27] develop a stochastic model for predicting the mortality for specific screening policies for breast cancer. They consider age-specific incidence and sensitivity. They use Breast Cancer

Surveillance Consortium (BCSC) data and conclude that initiating screening at age 40 instead of age 50 would lead to a small reduction in mortality.

Tsodikov *et al.* [30] consider breast cancer recurrence under a specific screening schedule. They build a stochastic model for the recurrence of a posttreatment cancer by assuming that the initial number of clonogenic cells follows Poisson distribution and the time until tumor recurrence from each clonogenic cell is identically distributed. They explicitly model cancer recurrence time and apply the optimization framework provided by an earlier article by Tsodikov and Yakovlev [29] to determine the optimal discrete-time cancer screening schedule that minimizes the expected delay time for the diagnosis of a recurrent cancer. They also perform a numerical analysis using BCSC data.

Baker [31] builds a stochastic model to evaluate the cost of screening and the cost of life-years lost due to breast cancer. The author measures costs such as screening costs in terms of months of life. Baker assumes one month of life is worth eight screenings. The author also assumes that ductal carcinoma *in situ* (DCIS) tumors, a noninvasive breast disease, are not harmful and thus can be ignored. The author evaluates a set of policies and concludes that the optimal screening policy should start at age 48, end at age 61.5, and should occur approximately every 2.5 years.

Günes *et al.* [32] develop a queueing model to investigate the impacts of various dynamic factors in mammography screening that are in interaction such as mammography reading volume and quality, access to screening, and delays in service. Their queueing model represents patients as the customers and radiologists as the servers, where the service capacity is limited. They also develop a simulation model. They minimize breast cancer deaths, while keeping system cost as a constraint. They find that improving the dissemination without an increase in the quality of the screening tests would result in excessive waste of resources.

Maillart *et al.* [33] develop a partially observable Markov chain model to investigate the relative value and frequency of

mammography screening for premenopausal women versus postmenopausal women. Their objective is to maximize the survival probability of a given patient. Using sample path enumeration, they evaluate 1223 policies, where each policy consists of two different screening intervals. They consider age-specific disease aggression and imperfect tests (both false-positive and false-negative test results). They show that screening should start at early ages and continue relatively late in life regardless of the screening intervals adopted.

Ayer *et al.* [34] develop a finite-horizon partially observable Markov decision process (POMDP) model to determine the optimal mammography screening strategy for an individual patient. The objective of this POMDP model is to find the optimal personalized screening policy that maximizes the total expected quality-adjusted life-years (QALYs) of a woman during her lifetime. They optimally solve this POMDP model using real data. They consider age-dependent disease progression and test accuracies as well as the possibility of self-detection. They show that the individualized personalized screening schedules outperform the existing guidelines with respect to the total expected QALYs, while significantly decreasing the number of mammograms. They further demonstrate that the mammography screening threshold risk increases with age. They also derive several structural properties of their POMDP model, including the sufficiency conditions that ensure the existence of a threshold cancer risk over which it is optimal to mammogram.

Ivy [35] builds a POMDP model that determines a cost-optimal screening and treatment policy from the payer's perspective while accounting for the patient's utility. The author assumes that both the likelihood of death from other causes and test accuracy are age-independent. The author discretizes the state space of the POMDP model, converts it into an MDP model, and solves this MDP using data from the literature. Ivy then presents the policy trade-off curves based on probabilities of *in situ* and invasive cancer while balancing payer cost and patient utility.

Chhatwal *et al.* [36,62] develop a finite-horizon MDP model to optimize breast-biopsy decisions based on mammography findings and demographic risk factors for women undergoing mammography. They compute the optimal biopsy decisions as a function of the probability of cancer while maximizing the total expected QALYs of a woman. They perform a structural analysis of the MDP model and prove several structured policies such as the optimal policy is a control-limit type for all ages (there exists a threshold probability of cancer such that it is always optimal to biopsy over that threshold) and the optimal control limit is nondecreasing with age. They use clinical data to solve the MDP model optimally and show that as women get older, the biopsy should be made less aggressively since women in older age groups benefit less from aggressive biopsying due to limited life expectancies.

Models for Colorectal Cancer Screening

The earlier studies on colorectal cancer (CRC) screening such as the studies by Eddy [63] and Eddy *et al.* [64] are described in previous review articles. Frazier *et al.* [37] compare the cost-effectiveness of several CRC screening policies suggested by several expert panels. They model the progression of CRC using a Markov process and develop a Markov-process-based simulation model to evaluate the performance of a given screening policy. They use data from literature and SEER database to simulate the US population by gender and age, and evaluate the performance of each screening policy. They perform extensive sensitivity analyses and report the best screening policies for each of these cases. They suggest the use of annual fecal occult blood test (FOBT) plus five-year sigmoidoscopy for CRC screening.

Preston [38] uses a continuous-time Markov process, an extension of the model described by Preston and Smith [39], to evaluate the performance of periodic screenings for a specific disease and a screening test with a particular sensitivity and specificity. The author models disease progression as an embedded Markov process with five system states. The author assumes that

the screening interval is constant (i.e., only periodic screenings are considered) and incorporates the total cost of cancer screening into the model. Preston also uses a parametric critical test value, a threshold that determines whether the test result is negative or positive. The author shows that the optimal combination of screening interval and critical test value minimizing the total expected cost of screening can be obtained by a nonlinear optimization model. The author presents numerical results for CRC screening when the only available screening modality is FOBT.

Clemen and Lacke [40] develop a simulation model by adding stochastic variables such as cancer dwelling time to an earlier deterministic model of Wagner *et al.* [65] and compare 30 different CRC screening policies. They use expert opinion and statistical methods to estimate the input parameters of the simulation model. They consider two criteria to compare various screening policies: number of prevented cancers and expected cost per saved life year. Their results show that undergoing colonoscopy every three years is the best screening policy.

Parmigiani *et al.* [41] develop a stochastic model to find the optimal timing of colonoscopy in a continuous-time setting in which individuals are examined only once in their lifetime. They derive a closed-form solution for the optimal timing of screening by maximizing a utility function which is equivalent to minimizing the probability of becoming infected before the screening examination. Therefore, they find the optimal time of screening by taking the derivative of this probability function. They assume that the sensitivity of the screening test is the same for all ages. They find that the optimal time for screening is at age 75 if the patient undergoes screening just once during his/her lifetime.

Leshno *et al.* [42] make a cost-effectiveness analysis for CRC screening for an individual with average risk of developing CRC. They build a POMDP model to represent the progression of CRC for a given screening strategy and use it to evaluate the performance of a set of common CRC screening strategies. They use data from the literature

to estimate the input parameters and perform an extensive numerical analysis, which suggests that the use of colonoscopy every ten years and the use of annual FOBT plus five-year sigmoidoscopy are the most cost-effective two strategies.

Harper and Jones [43] consider the problem of determining the best screening policy for an average patient using semi-Markov process and simulation models. They develop a five-state semi-Markov process model using general transition time distributions. They show how to calculate the probability of early polyp and cancer detection given that the time between two consecutive screenings is constant. The authors do not provide any numerical results for the semi-Markov process model; instead, they present a detailed simulation model where disease progression is modeled as a semi-Markov process. The state space of the simulation model consists of conventional cancer states (clean, polyp, cancer) and metastatic CRC state. They utilize clinical data from European health institutions to evaluate and compare six different screening policies with respect to several criteria such as mean survival time from CRC diagnosis, percentage of detected polyps, cancers, etc.

Yaesoubi and Roberts [44] develop a sequential game theory model with perfect information to analyze the decisions of an insurance company for covering CRC screenings. The insurer decides which screening alternatives to cover, how much the insurance premium would increase to cover CRC screenings, and how much the insurees would have to pay to cover recommended screenings. The insurer's objective is to minimize a weighted average of the total screening/treatment cost and total QALYs of all of the patients (a negative term). In return, the insurees choose the screening alternative that maximizes a utility function of screening cost and their total QALYs. The authors assume that the decisions are made every 10 years. They also assume that patients have perfect information about the progression of the CRC and are able to estimate their total expected QALYs. They use a simulation model and clinical data to estimate the progression of CRC under

certain screening alternatives. The details of this simulation model are explained in another related paper by Roberts *et al.* [72]. Yaesoubi and Roberts assume that the patients belong to the two risk groups (low and high risk) and they consider only two screening alternatives: FOBT and colonoscopy. Their numerical results show that covering CRC screening, especially for low risk patients, is not economically attractive for the insurer unless the insurer's valuation of QALY is very high.

Erenay and Alagoz [45] develop a finite-horizon POMDP model that can be used to obtain a patient-specific optimal lifetime screening policy. They use two optimization criteria: total expected QALYs of the patient and total cost of screening and treatment. They consider the effect of age, gender, and personal CRC history on CRC progression. They model patients with both low and high risk of developing polyps, the precursor of CRC, separately. They also account for the secondary occurrence of CRC, which enables the model to determine the optimal screening policy for CRC surveillance. They perform a numerical analysis by using data from SEER database, clinical databases, and literature.

Models for Cervical Cancer Screening

The earlier studies on cervical cancer screening such as Lincoln and Weiss [66], Eddy [67], Habbema *et al.* [68], and Boyd *et al.* [69] were described in previous survey articles in detail. Myers *et al.* [46] develop a Markov model that represents the natural history of the human papillomavirus (HPV), the primary cause of cervical cancer, and cervical cancer under a specific Pap smear screening. They use the Markov model to analyze the effects of different screening interval choices on cervical cancer incidence for a cohort population. They vary starting age for screening to evaluate the performance of screening policies using Pap smear test with 1-to-5-year intervals and compare them to no screening. They show that as the screening intervals decrease, the performance of the screening improves. However, the benefit of more frequent screening reduces for women over a threshold age. They also note that the performance difference is insignificant if the

screening starts at a very early age such as 15–25.

There are several other studies that analyze the effect of HPV screening and prevention techniques on cervical cancer prevention, by using Markov models. Goldie *et al.* [47] evaluate the cost-effectiveness of the HPV DNA test in addition to conventional cytology tests scheduled according to the national guidelines. Kulasingam *et al.* [48] consider whether adding HPV vaccination to the cervical cancer screening policy suggested by national guidelines as compared to screening alone is cost-effective or not. Their numerical results show that both DNA test with conventional screening and vaccination with conventional screening are, cost-effective when compared to conventional screening alone.

Models for Screening Other Cancers

Tsodikov and Yakovlev [29] consider the problem of optimizing cancer screening schedule for a given patient and apply their theoretical findings to lung cancer screening. They classify the health states as disease-free, infected, and heavily infected. They perform an analytical study by developing a stochastic model that optimally schedules cancer screenings over a given decision horizon for given data. They first assume that the number of total screenings is fixed and minimize the total expected delay time to diagnose the cancer. They then relax this assumption and minimize the total cost of cancer screening by assigning a unit cost for delay time to cancer detection. They further assume that there is no symptomatic diagnosis and cancer diagnosis probability after screening increases with time within the same health state. They derive several structural properties of the optimal screening schedule such as the existence of an optimal periodic screening schedule when the total number of screenings is fixed.

Pinsky [49] develops a natural history model for a specific disease and measures the performance of a screening policy for a target population. The author develops a five-state convolution model by relaxing the Markovian assumption in Chen *et al.*'s [70] five-state Markov process model. Pinsky demonstrates the computation of the expected number of

screen-detected preclinical and clinical disease states given a specific screening program and provides closed-form solutions for various components of the model such as sojourn time and over-diagnosis rate. The author uses data from literature and Mayo Lung Cancer Screening Trial (MLCST) [71] and performs a numerical analysis for lung cancer, which shows that the model's results fit well to the MLCST. The author also investigates how screening interval affects the model's outputs. For example, the author shows that lead times are not affected by changes in screening interval whereas the proportion of the cohort ever diagnosed with late-stage lung cancer is very sensitive to the screening intervals.

Tsodikov *et al.* [50] use a three-stage stochastic model to represent prostate cancer progression under a PSA screening program. They explicitly formulate certain characteristics of the prostate cancer progression including mean lead time, prostate cancer incidence under a given screening program, and over-diagnosis rate for each patient type and representative population. They then use SEER data to perform a numerical analysis and estimate these characteristics for prostate cancer.

Kent *et al.* [51] develop a nonlinear optimization model to determine the optimal time for the bladder cancer screening from the physician's perspective. They optimize the expected detection delay while minimizing the probability that the cancer spreads to other parts of the body. They assume that only a limited number of screenings is available and recurrence of tumors follows a Poisson process. They further assume that the screening tests are perfect. They conclude that their proposed screening policy would save three weeks of delay in detection when compared to clinical practice.

Havrilesky *et al.* [52] build a Markov-process-based simulation model to estimate the cost-effectiveness of various screening strategies for ovarian cancer. They use age-specific incidence and mortality rates from SEER data. Their outcome measures include mortality reduction, number of false-positive tests, positive predictive value, years of life saved, lifetime economic costs, and incremental cost-effectiveness

ratio. They conclude that annual screening is cost-effective and cost-effectiveness of screening is most sensitive to test frequency, specificity, and cost.

Davies *et al.* [53] build a discrete-time simulation model to measure the performance of a screening program against *Helicobacter pylori* infection, the primary cause for gastric cancer, in England and Wales, where individuals under age 50 would be screened only once. They use data from the literature and the simulation model to estimate the reduction in mortality due to the screening program and the cost of the program. They report sensitivity analyses for five parameters with high uncertainty.

FUTURE RESEARCH IN CANCER SCREENING

Cancer screening is very controversial with many open research questions such as when to start and end screening? How often should a target population undergo a particular screening modality? Is the use of dynamic screening interval/policy a better strategy than the current screening recommendations using static screening strategies? How can a more personalized screening policy based on individual risk factors be implemented? What would be the effects of requiring some patients to use more expensive but more sensitive screening modalities? Is it cost-effective to use a new screening technology over an existing one? What are the mortality and morbidity benefits of a particular screening program?

Because of its importance, there is a growing interest among operations researchers in studying the cancer screening problem. As Maillart *et al.* [33] note, there are two approaches taken in quantitative cancer screening models. On one extreme, which is taken by most studies in the literature, empirical, cost-effectiveness simulation models based on clinical trials and clinical data are used. A simulation model can be used to find the best strategy that maximizes an objective by testing all reasonable screening strategies and comparing their outcomes. This is feasible only when the number of reasonable screening policies is very small.

However, the number of possible screening policies (due to open questions such as when to start and end screening, what should be the optimal screening interval for different risk groups, which screening technology should be used for which type of patients) increases dramatically and hence the computation of all cost-effective strategies becomes intractable.

At the other extreme, analytical models are utilized, which have several modeling limitations. For instance, most of these studies do not perform extensive numerical analyses using reliable real clinical data. In particular, while several researchers solve their analytical models using data from the literature, some of the data sources include unreliable/inaccurate estimations, which may affect the policy recommendations made by these studies. The validation of the data used in these studies is typically missing whereas it is of crucial importance. Furthermore, the existing studies make several unrealistic assumptions by ignoring important factors affecting the screening decisions. For instance, many studies consider only fixed screening intervals (i.e., the screening interval does not depend on the results of the previous screening tests) whereas the screening policy should consider the results of the previous tests in making further screening recommendations.

Moreover, several studies do not explicitly model precursor states, which is very critical in modeling diseases (such as CRC) that have a precursor clinical state (such as polyps in CRC) which progresses to cancer with time. That is, certain cancer types may not be represented properly with these models. Because removing such precursors affects further cancer development, any realistic model should consider them explicitly. Most researchers assume constant screening test accuracy, that is, the accuracy of the screening tests does not depend on age. Similarly, several studies assume that the disease aggression does not change with age although there is strong evidence that the progression of the diseases is highly age-dependent.

In addition to these common limitations of the existing studies, some of the other limiting assumptions in these models include

the following: the number of the susceptible people in the population is constant and the incidence rate is time-stationary; the time in preclinical state is exponentially distributed; the risk of cancer is the same for all population; the number of available screening tests is equal to one; screening tests are perfect; tumor recurrence follows a Poisson process; self-diagnosis of diseases (such as breast cancer) is not possible; the disease mortality does not change with age.

Although the validation of OR models constitutes a barrier for their policy implementation, mathematical modeling is an essential tool for planning and improving cancer screening due to the complexity of the cancer screening problem. Future research in cancer screening may need to combine the two approaches described earlier. Furthermore, there is also a strong need to develop models without making any unrealistic assumptions, such as the ones listed earlier. Another important issue in cancer screening studies is to conduct numerical analyses using reliable data. Fortunately, there are many statistical modeling approaches in the literature that study disease progression and treatment decisions more rigorously. Combining the OR methods with statistical tools that analyze real clinical data more rigorously is another promising area of research. Considering huge economic cost of and lives lost due to cancer, more research is needed to design better screening programs, the most cost-effective means for controlling this disease.

HISTORY OF THE OR SOCIETY IN CHINA

Modern OR activities in China were initiated in the late 1950s as the first OR group was founded at the Institute of Mechanics, Chinese Academy of Sciences (CAS) in 1956, promoted by Profs H.S. Tsien and K.C. Hsu. Tsien received his Master's degree from MIT and his Ph.D. from the California Institute of Technology, and went on to become Cal Tech's first Goddard Professor. Hsu earned his Ph.D. at the University of Kansas, and was a research associate in the Institute of Fluid Mechanics and Applied Mathematics at the University of Maryland. Tsien and Hsu returned to China in 1955.

By 1959, a second OR division was set up at the Institute of Mathematics, CAS. These two divisions merged into one research department in the Institute of Mathematics in 1960. The main research interests at that time were queueing theory, nonlinear programming, and graph theory along with transportation theory, dynamic programming, quality control, and economic analysis.

*Part of the historical review of ORSC is from an article by Xiang-Sun Zhang and Kan Cheng, "China: Ancient Country Makes OR History," *OR/MS Today*, October 1998.

In 1963, the division organized a series of specialized courses in OR at the Chinese University of Science and Technology, marking the first time in China that a university offered a systematic education in OR. Today, OR courses are a basic requirement in the business schools and engineering departments of almost every university in China.

Early OR application activities (late 1950s) in China focused on transportation problems. One such example was the allocation design of threshing grounds to save time and manpower. The classic Chinese postman problem model was presented by Gwan [1] in the same period.

One of the early highlights of OR application activities in China was conducted by the Chinese mathematician L.G. Hua, a member of CAS and president of the Chinese Society of Mathematics, during the so-called *Great Cultural Revolution*. Since theoretical research had been stopped at that time, Hua formed his own small group and turned to teaching basic optimization techniques at countryside factories in an effort to help managers and engineers apply OR in their daily operations. For a decade, beginning in 1965, Hua visited more than 20 provinces and innumerable towns and cities with his group and planted the seeds of OR principles and philosophies wherever he went [2]. His work promoted the development of OR in China then and continues to this day, long after his death.

The Operations Research Society of China (ORSC) was founded after the Great Cultural Revolution in 1980 when the First National Conference of OR was held in Shandong Province (on the east coast). Hua was elected the first president of ORSC. ORSC became a member of IFORS in 1982. Since the 1990s, ORSC has been active in the development of the Association of Asia-Pacific Operational Research Societies (APORS) within IFORS. As the president of APORS from 1991 to 1994, Professor Guanghui Hsu (ORSC president 1988–1996) organized the second conference of APORS in Beijing in the fall of 1991. As a representative of APORS, Hsu also served

as vice president of IFORS from 1992 to 1994.

As the most important events, ORSC convenes quadrennial national meetings, in which new president and its committee members, as well as officers, are elected for a term of four years. The most recent quadrennial meeting was held in 2008 in Nanjing and attended by over 450 participants. The national congress has traditionally been convened every four years, supplemented by a biannual academic conference. The Congress featured plenary talks, paper presentations, the ORSC election, prize awarding, and committee meetings. ORSC2008 awarded, for the first time, the Science and Technology Award of ORSC to Professor Minyi Yue, who was the president of ORSC from 1984 to 1988. It also marketed the first attendance of an IFORS president in the event. Other guests invited in the past include Sun Joo Park from Operations Research Society of Korea, Toshiharu Hasegawa and Masanori Fushimi from Operations Research Society of Japan (ORSJ) as well as Charles Larson and Mark Daskin from INFORMS.

It was ORSC's pleasure to host the IFORS 15th Triennial Conference in Beijing, since it was an opportunity for Chinese OR workers to learn about the new developments and trends of OR in other countries, especially in the developed countries. Since IFORS99 in Beijing, ORSC events have become more international and attracted more young operations researchers. The majority of its more than 1300 members come from universities and research institutes. ORSC plans to play an active part in getting OR applied in industry and be relevant to the rapidly developing economy of China. A step in this direction can be seen in the election into the ORSC council of more representatives from the consulting and financial arenas.

The ORSC now has 1350 qualified members and a dozen chapters located throughout the vast country. To obtain a membership, one just needs to send a request to the ORSC secretariat (orssc@amt.ac.cn), subject to annual membership fee RMB 40 Yuan (or US\$6).

Academically, there are 13 special committees (or subsocieties) under ORSC:

- Mathematical Programming

- Queueing Theory and Applications
- Reliability Theory
- Decision Making Theory and Applications
- Uncertainty Systems
- Intelligence Computing
- Scheduling Theory
- Graph Theories and Combinatorics
- Fuzzy Information and Engineering
- Game Theory and Applications
- Financial Engineering and financial risk management
- OR for Enterprise
- Computational Systems Biology

They organize symposiums every year or every other year during the interval of the two national conferences. Many of the committees and local branches present prizes recognizing outstanding work.

To promote cooperation with OR colleagues in the Asia-Pacific area and the rest of the world, the Asia-Pacific Operations Research Center (APORC) was set up in 1995 in Beijing. The center is affiliated with the CAS and APORS. APORC has already organized eight symposiums titled "International Symposium on Operations Research and Applications in Engineering, Technology, and Management (ISORA)." The upcoming ninth ISORA2010 is to be held in Jiuzhaigou, a world-famous natural reserve in China's south western Sichuan province. These symposium proceedings are published in the series of "Lecture Notes in Operations Research."

STATUS OF ACADEMIC RESEARCH AND APPLICATION OF OR IN CHINA

During the 1980s, many universities and colleges started to set up OR courses in their engineering schools, business schools or economic management schools. Linear programming, nonlinear programming, networks, queueing theory, reliability theory, inventory, and other major OR techniques are all taught at various levels. OR degrees (MS and PhD) are offered in some universities and institutes such as Tsinghua University, Chinese University of Science

and Technology, Fudan University, and some institutes in CAS such as Institute of Applied Mathematics and Institute of Systems Science.

ORSC has two official journals: *OR Transactions*, a quarterly journal that publishes original articles in OR and related fields (papers are published either in Chinese or English); and *OR and MS* (in Chinese only), a bimonthly aims at OR practitioners. Two journals sponsored by CAS—*Acta Mathematicae Applicatae Sinica* and *System Science and Mathematics*—also accept OR-related papers.

There are two major avenues for OR researchers in China to obtain grants. The first is through the National Natural Science Foundation of China (NSFC), which has given about one-third of its total funds for mathematicians to researchers involved in OR mathematics. Researchers can also apply for grants from other branches of the NSFC such as Management Science, Information Science and Engineering.

The second means to obtain grants is by providing consulting services to the public sector such as the central government, local government, industrial sectors, and so on. In these applications, traditional OR models and algorithms are built into software, and sometimes a complete management information system or a decision support system with OR-type philosophy and algorithms at its core are provided to the user.

One such example, a “Project Evaluation System in the State Economic Information System of China,” by Profs X.S. Zhang and J.C. Cui from the OR Division of Institute of Applied Mathematics, CAS, [3] won the IFORS Prize for OR in Developing Countries at the 14th Triennial Conference in Vancouver, Canada. The core part of the project is a reverse model of Data Envelopment Analysis (DEA).

Most OR activities in China have their foothold in industrial and agricultural applications, such as applications in petrochemical enterprises, manufacture engineering, and structure design of products. Some OR practitioners have focused their attention on supporting high-level

government decision makers in their strategic planning about the country’s continued advance in economy and ecology. The project, “Optimization of the Ecological Economic Development for the Upper Reaches of the Yangtse River,” by Prof. G.Z. Liu and his colleagues from Chengdu University of Science and Technology, was awarded the second place prize in the IFORS Prize for OR in Developing Countries competition. Another OR research project which had great social influence in China is “Grain Output Forecasting” conducted by Prof. X.K. Chen from the Institute of Systems Science, CAS [4]. With an input–occupancy–output technique at its core, the project has greatly increased the accuracy of the national grain output forecast. The group and its achievement received accolades from top government officials as well as CAS, which awarded the group its highest prize. Remarkably, Profs Yaxiang Yuan and Yuhong Dai’s recent research results [5–9] on nonlinear optimization theories and computational methods won the runner-up prize of the China National Natural Science Prize, which is one of the top scientific achievements recognized by the Government of China. Recently, Shouyang Wang and his research group [10] show that OR techniques play an important role in China’s reaction to the world financial crises.

2010 marks the 30th anniversary of the OR Society of China. The society is going to have a national meeting ORSC2010 in October in Beijing. Varied events have been planned to celebrate the rapid development of OR researches and applications in China over the past thirty years. ORSC is going to host APORS2011 in China’s Xi’an, a return of APORS triennial conference back to China after the second conference in Beijing in 1991. Chinese OR community is prepared to welcome colleagues from around the world as they are making ever greater efforts to contribute to the rapid growing economy.

OPERATIONS RESEARCH SOCIETY OF NEW ZEALAND

ANDREW MASON
Operations Research Society of
New Zealand, Auckland,
New Zealand

The Operations Research Society of New Zealand (ORSNZ) was created on 24 May, 1965 when the Society was legally incorporated at the New Zealand Companies office. The Society was founded by staff at the Applied Maths Division of the Department of Scientific and Industrial Research (DSIR), a government department based primarily in Wellington, New Zealand. Known originally as the Operational Research Society of New Zealand, the “Operational Research” was changed to “Operations Research” in 2009 to reflect the now more popular term in New Zealand. The Society’s logo is shown in Fig. 1.

GOALS AND MEMBERSHIP

Formally registered as a charity in 2008, the ORSNZ is a nationwide not-for-profit organization with approximately 150 members including public servants, academics, students, consultants, and practitioners in industry. The Society’s membership also includes several companies active in operations research. The primary aim of the Society is to promote operations research and management science in New Zealand in both academic and industrial aspects. The ORSNZ is affiliated to the Association of Asia Pacific Operational Research Societies (APORS), the International Federation of Operational Research Societies (IFORS), and the Royal Society of New Zealand (RSNZ).

The Society’s activities include publishing a regular newsletter, organizing branch meetings in Auckland, Wellington, and Christchurch, hosting visitors to New Zealand, maintaining the web site (www.orsnz.org.nz), and organizing an

annual conference. The Society published the New Zealand Operational Research (NZOR) journal from September 1971 until July 1986 when NZOR merged with the Asia Pacific Journal of Operational Research (APJOR).

ANNUAL CONFERENCE AND VISITOR PROGRAM

The Society runs a two-day conference in late November or early December each year. The 40th such conference was held in December 2005 at the Society’s birthplace, Victoria University, Wellington. The conference location rotates between the University of Auckland, the University of Canterbury in Christchurch, and the University of Victoria in Wellington. Proceedings of the conference are published and posted to members, and also made available on-line on the Society’s web site.

A highlight of the conference is the Young Practitioner Prize (YPP) awarded for the best lecture given by a presenter under 30 years of age. Students and recent graduates are supported and encouraged to attend conferences by free registration, generous prize money for the YPP, and grants to cover travel expenses.

The Society encourages and financially supports international visitors to give plenary addresses at the conference. Recent plenary presenters include Dorit S. Hochbaum (USA) in 2009, Craig MacLeod (NZ) and Anita Schöbel (Germany) in 2008, and Michael Trick (USA) and Gerard P. Cachon (USA) in 2007. In 1985, the Society was honored to welcome George Dantzig as a guest at its 21st conference celebrations.

To further support international visitors, the ORSNZ invites nominations for ORSNZ honorary visiting lecturers to visit New Zealand. Each visiting lecturer is expected to give a lecture on some topic likely to be of general interest to ORSNZ members at three or more locations among Auckland, Hamilton, Wellington, and Christchurch. The ORSNZ contributes to the travel costs for

Figure 1. The ORSNZ logo.

this visit. Recent visitors include Ted Ralphs from Lehigh University, Michael Trick from Carnegie Mellon University, and Anita Schöbel from the University of Göttingen.

DAELLENBACH PRIZE

To honor the considerable contributions of Emeritus Professor Hans Daellenbach to operations research/management science in New Zealand, the ORSNZ established the ORSNZ Hans Daellenbach Prize in 2001. Professor Daellenbach's contributions reflect his belief that the best work in operations research combines strong innovative methodology with practical impact. The Daellenbach Prize is awarded for a body of work that has made a significant contribution and received international recognition. The inaugural prize was awarded to Professor David Ryan, University of Auckland, in 2001, for his work on scheduling problems and their application to crew scheduling and other problems at Air New Zealand. In 2003, the award went to Professor Les Foulds, University of Waikato, while in 2006 Professor Andy Philpott won the award for contributions ranging from yacht design with Team New Zealand, through telecommunications network design to the analysis of electricity markets and the optimization of electricity generation

Table 1. Recent Presidents of the ORSNZ.

1994–1996	Jonathon Lermitt, Transpower, Wellington
1996–2000	Andy Philpott, University of Auckland
2000–2003	Les Foulds, University of Waikato
2003–2007	David Ryan, University of Auckland
2007–	Andrew Mason, University of Auckland

and transmission. Perhaps as a reflection of the strong emphasis placed in New Zealand on using operations research to make a practical difference, Professors David Ryan and Andy Philpott have both been finalists in the prestigious international INFORMS Edelman prize, as has fellow ORSNZ member Professor Mikael Rönnqvist.

ORSNZ MANAGEMENT

The Society is run by an elected Council comprising a President, a Vice President, an Honorary Secretary, an Honorary Treasurer, and six other members. Recent presidents of the Society are listed in Table 1.

In accordance with legal requirements, the Society holds Annual General Meetings to present its accounts to members and discuss business and other matters. These meetings typically take place during the annual conference.

Further information on the ORSNZ can be found on the Society's web site, <http://www.orsnz.org.nz>. The author acknowledges this site as a source for much of the information included in this article.

OPERATIONS RESEARCH SOCIETY OF TAIWAN

HSING LUH
Department of Mathematical
Sciences, National Chengchi
University, Taipei City,
Taiwan

SUMMARY

Before starting to introduce the Operations Research Society of Taiwan, a short summary of Taiwan's economic and educational background is given for a better glance of its industrial and academic environment. Taiwan includes a population of 23,046,177 people as registered in 2009. The capital city is Taipei, which is located off the coast of mainland China. Real growth in GDP has averaged about 8% during the past three decades. Exports have provided the primary forward motion for industrialization. The trade surplus is substantial, and foreign reserves are the world's fifth largest as of December 31, 2007. Leading technologies of Taiwan include: bicycle manufacturing, biotechnology, semiconductor device fabrication, laptops, and smart phones; for example, Giant Bicycles, Merida, Acer, Asus, BenQ, HTC, and so on [1].

During the past 20 years, Taiwan has become a major foreign investor in mainland China, Thailand, Indonesia, the Philippines, Malaysia, and Vietnam. It is estimated that some 50,000 Taiwanese businesses and 1 million business people and their dependents are established in the People's Republic of China (PRC) [2]. Growth averaged more than 4% in the 2002–2006 period and the unemployment rate fell below 4%. Since the global financial crisis starting with United States in 2007, unemployment rate in Taiwan has risen to over 5.9% and economic growth has fallen to –2.9% [3]. As of December 2008, there were 1,337,455 students enrolled in

167 colleges (universities): 17% studying the humanities, 36% social science, and 47% science and technology. Of the more than 6000 academic departments or programs, almost 28% of students were studying technology and engineering; 2% mathematics- and statistics-related areas; and 13% general management [4].

For a long time, the methodologies of operations research (OR) have been adopted as analysis tools for production efficiency in business and industry in Taiwan. In a survey by Kuo and Liu [5], it was found that there were 59.30% of the methodologies were used in production, 57.56% in finance, 48.26% in marketing, 35.47% in human resource, and 53.49% in information. The specific OR subjects involved were linear programming (28.49%), network analysis (34.30%), other mathematical programming (18.02%), queueing models (10.47%), Markovian decision processes (4.65%), other probability models (40.12%), decision theory (27.91%), simulation (30.23%), statistical forecasting (64.53%), and in decision analysis with computers (70.93%).

THE SOCIETY

Because of its high demand in education and practice, setting up of an OR society was proposed in 1996 when many OR professionals, including professors, engineers, and managers called for an exclusive professional society. As per the law regarding professional societies in Taiwan, numerous meetings were initiated by the founding members; these took place in Taipei, Hsin-chu, Taichung, and Kaohsiung. Finally, two formal meetings were held at the Department of Mathematical Sciences in National Chengchi University, Taipei and Department of Industrial Engineering and Enterprise Information in Tunghai University, Taichung on April 26 and July 12, 2003, respectively. The testimonial events generated an enthusiastic exchange of ideas and culminated in the formation of a

working committee whose task was to define the organization that was to be the Operations Research Society of Taiwan (ORSTW), which is also responsible for the INFORMS Taiwan Chapter (INFORMS TWC) with the same committee members. On September 13, 2003, the committee presented the constitution and by-laws for approval by the first founding meeting of some 150 members, and the ORSTW formally came into being. Finally, ORSTW/INFORMS TWC has been officially at the forefront of promoting the advancement and practice of OR in Taiwan.

The officers of the society include the president, secretary, treasurer, and executive board. The terms of the president, secretary, treasurer, and board of executives is two years from the time of election. Up to now, the presidents and their terms of office are Dr. Ping Teng Chang, Professor at Department of Industrial Engineering and Enterprise Information, Tunghai University, 2003–2005; Dr. Hsing Paul Luh, Professor at Department of Mathematical Sciences, National Chengchi University, 2005–2007; Dr. Sy-Ming Guu at College of Management, Yuan Ze University, 2007–2009.

The logo of ORSTW depicted in Fig. 1 was presented and approved unanimously in the first annual meeting while its website was given at www.orstw.org.tw for advertisement and communication. Besides local and foreign experts who have presented papers featuring OR applications in various sectors, Ph.D. and Master's thesis competitions and working project competitions have been initiated for college students. This has become a regular event of the society in its drive to focus on the vast potential of OR in Taiwan. At about the same time, the call for papers for the first issue of the International Journal of Operations Research (IJOR) was brought out.

IJOR reports on developments in OR, information systems, and management sciences, including the latest research results and applications. Its aim is to meet the needs of accelerating technological change and changes in the global economy. It is available in abstracting/indexing services including Mathematical Reviews, EBSCOhost, Index of Information Systems Journals, CSA's

Technology Research Database, CSA's Engineering Research Database, CSA's Industrial and Manufacturing Engineering Database, Zentralblatt MATH, INSPEC. Twenty issues have been published since 2004 with both a regular print version, ISSN: 1813–713X, and an on-line version, ISSN: 1813–7148 [6].

Each year, the ORSTW's general membership meeting serves as a forum to discuss pertinent issues and new directions. Both academic and professional development programs are scheduled for its members through a paper presentation and project competition on issues such as traffic, agriculture, environment, energy, supply-chain management, and business logistics. Public service was also established to move closer to the long-term mission of helping in nation-building through the use of OR. Several projects have been incorporated with semiconductor manufacturing, transportation, and financial services. Workshops of OR methodologies have been organized with European and American universities to provide short-term or summer programs for Taiwanese college students as well as teachers to update their OR knowledge for future research and development. Since 2003, the membership has been growing by 15% due to the aggressive promotion and attractive activities.

The ORSTW's executive board was founded by 20 members and consists of five members in the board of supervisors; they are selected among all members biannually in the general membership meeting. The mission of the executive board includes the following:

- *Offer More Products and Services to the Practice Community.* ORSTW looks

Figure 1. The logo of the Operations Research Society of Taiwan.

across the whole set of interrelationships in the field while strengthening as well as balancing both sides between academia and industry. If ORSTW develops only strong academics without any link to the real-world, that would make no difference with pure theory analysis, such as mathematics. To understand the whole value chain, ORSTW needs to pay more attention to real-world problems. Therefore, in the annual ORSTW conference each year, more than half of the contributed sessions are reserved for practitioners. Besides, the committee encourages joint professional activities with Taiwanese enterprises by providing more management consultancy and services for them.

- *Boost Worldwide Recognition for the Profession.* It has tremendous opportunities to identify new practitioners and practice-related activities that have not necessarily been in the OR field in the past. ORSTW feels there are more possibilities that should be explored in those areas. For example, because of the emergent internet economy, finding more ways to put cutting-edge research into use is challenging and promising.
- *Identify New Initiatives to Take the Profession and the Organization Forward.* To appreciate the value chain created by OR professions, ORSTW needs to create a virtuous circle which not only brings new people and programs into ORSTW, but also makes the people and programs we already have even better. Thus, ORSTW is responsible for initiating any possible force and providing the momentum to take it forward.
- *Launch New Publications.* It is a very long and difficult process to start a new academic journal, but IJOR has been successfully published as a significant example. It needs to start thinking about new publications and journals and how ORSTW delivers them. To increase the presence of journals and services in China, India, and other emerging economies, ORSTW should

make it available for edited book volumes or on-line compilations.

- *Increase Membership.* ORSTW should have provided tremendous value to our academic members because of regularly published IJOR and annual conferences. But it is not enough. Many people doing things called “analytics” or some other name have not traditionally been allied with OR and management science. ORSTW should offer them the services, products, networking opportunities, and other things that they value and help them to be more effective professionally, so that we can really contribute to the growth of this organization. ORSTW should bring new membership for circulating the process to achieve better.
- *Improve Governance.* ORSTW keeps working to improve mechanisms to deal with building a strong organization. ORSTW receives enormous help from volunteers every year. Teachers, students, and practitioners have made great contributions toward planning, prioritizing and steering the organization. ORSTW should enhance strengths by identifying areas for growth and new opportunities.
- *International awareness.* ORSTW is working collaboratively with OR societies all over the world. ORSTW members have been actively involved in meetings among INFORMS, Asian Pacific Operational Research Societies (APORS), International Federation of Operational Research Societies (IFORS) and so on. Joint conferences with transportation, science and technology, service and military, and many other professional societies have taken place with mutual research and interest. Societies from Japan, Korea, Hong Kong, USA, and others have worked closely with ORSTW for general conferences. In December 2007, the ORSTW hosted its first group of Chinese OR scholars from mainland China at the fourth annual meeting.

THE FUTURE

Information technology is transforming the world. There are tremendous opportunities out there for OR in both education and industry. ORSTW and INFORMSTWC will work together to provide more services for OR professions, as well as academia and industry. With its rich past and strong support, ORSTW indeed has a lot to look forward to for its promising development.

INTRODUCTION

From improving the performance of fire and police departments, optimizing the public transportation system, programming delivery of blood to hospitals, planning housing projects, and analyzing drug policies to improving delivery of meals to senior citizens, there are many examples of how operations research (OR) addresses community needs [1]. Public sector OR deals with solving public interest problems through the application of analytical tools. One of the public sector OR application areas is humanitarian OR, which particularly deals with the problem of delivering relief to people affected by a disaster. Hence, natural and man-made disasters are the most common subject of attention for humanitarian OR.

There were 6637 natural disasters between 1974 and 2003 worldwide, with more than 5.1 billion affected people, more than 182 million homeless, more than 2 million deaths, and with a reported damage of US\$1.38 trillion [2]. In 2005 alone, over 180,000 deaths and US\$200 billion economic losses have occurred due to disasters according to the Disaster Resource Network Humanitarian Relief Initiative [3]. The September 11 attacks (2001), tsunami in South Asia (2004), Hurricane Katrina (2005),

and earthquakes in Pakistan (2005) and Java (2006) are just some examples of the deadliest disasters witnessed by humankind in the past few years.

The consequences of these events are enormous, not only in the short term with injuries, loss of life, and damaged infrastructure, but also in the long term with changes in social and economic conditions. Even though the occurrence of these events could not have been avoided, the impact could have been reduced by different means including humanitarian OR. For example, adequate warning systems could have prevented injuries and fatalities during the 2004 tsunami, and help could not reach Pakistani earthquake victims because of logistics difficulties with limited infrastructure. Humanitarian OR differs from other OR applications because it deals with particularly unique and highly variable events, often in resource-poor and limited-infrastructure environments, with multiple organizations trying to work together in response activities simultaneously. These factors increase the complexity of responding to these events.

The focus of this article is on supply chain-related issues in humanitarian operations, with a greater focus on “disasters” rather than ongoing conditions. We discuss differences between regular supply chains and supply chains used for disaster planning and response, that is, “humanitarian supply chains”. First, we describe characteristics of supply and demand of disaster supply chains, followed by a discussion on the particularities of the execution and management of these supply chains. Next, an application of OR in humanitarian operations is examined in more detail, and finally main challenges and future research directions are presented.

OVERVIEW OF DISASTERS

Disasters can be grouped into two main categories: natural and man made.

Table 1. Disaster Categorization and Examples

	Man-made	Natural
Slow onset	Political crisis, refugee crisis	Famine, drought
Sudden onset	Terrorist attacks, chemical leaks	Hurricanes, floods, earthquakes, tsunamis

Natural disasters are the consequences of natural hazards that affect people, whereas man-made disasters are caused by human actions. A more detailed categorization of disasters is shown in Table 1 along with examples. Also, disasters could be categorized in predictable timing (or seasonal) such as floods or unpredictable timing like earthquakes; and predictable location such as hurricanes or unpredictable locations like tsunamis.

No matter what the type of disaster, the management of these events typically follows four sequential stages: mitigation, preparedness, response, and recovery. Mitigation is the application of actions to help prevent or reduce the hazards of the disaster. It differs from the other stages because it focuses on long-term measures for reducing or eliminating risk [4]. Preparedness activities help prepare for response once a disaster occurs. The response phase covers activities for mobilizing emergency responders and services for the affected region. Recovery is the stabilization phase during which restoration of the disaster area is conducted

in the long term. The disaster management timeline with the related operations can be seen in Fig. 1.

There has been some research on the use of OR techniques in disaster management. Altay and Green [5] survey the literature and summarize the research in this area. Most of the papers published deal with man-made disasters (47.6%) or general disaster operations management (40.5%). Among the papers reviewed, 61.1% are on the pre disaster phase (mitigation and preparedness) and mostly based on risk analysis, 23.9% are on response, and only 11% are about recovery. More than half of the research is based on model development, followed by theory and application development. Most of the application studies are made for the disaster phase, whereas the theory papers mostly focus on the pre-disaster phase.

SUPPLY

A primary role of a supplier in a supply chain is to source the required items downstream. The main sources in a humanitarian supply chain are vendors and donors. Vendors can be local to the region where the disaster occurred, or global. Donors are the sources of donations of any type (financial, products, services, etc.).

Supplies consist of relief items, personnel/volunteers, and transportation and construction resources, among others. Most of the supplies fall into the relief items

Predisaster	Disaster	Postdisaster
Mitigation and preparedness	Response	Recovery
Assessment Risk factors Vulnerability	Relief operations: First phase Medics, food, and shelter	Debris cleaning Infrastructure rebuilding Re-establishing communities
Planning Infrastructure Policy making Capacity building Prepositioning resources	Second phase Housing Food supply chain building	Measure the effects of: Infrastructure Planning Response short and long term
Training/education	Logistics stages: Mobilization and procurement Long haul The last mile	Lessons learned, feedback to planning and response

Figure 1. Disaster timeline and operations.

category. Figure 2 shows a categorization for relief items, as well as some examples. Consumable relief items require recurrent delivery to the affected community, and non-consumable relief items require a one-time delivery only. Nonconsumable operational relief items are required to set up an operation, while nonoperational items are required to meet the essential needs of the affected population.

There are specific challenges related to supplies that come from in-kind donations. First, since the quantity and mix of the supplies depend at least to some degree on the donor, there is a high uncertainty of what is going to be received. Moreover, the timing of these supplies might not be appropriate: for example, consumables that arrive too early cannot be stored for a long time, or nonconsumables that arrive after the operation was set up are wasted. There are many cases in the recent history where donated items were not needed and were not deployed to people affected by the disaster. Autier *et al.* [6] discuss the case of drug supplies after the 1988 Armenian earthquake, when at least 5000 tons of drugs and consumable medical supplies were sent by international relief operations, but only 30% were immediately

usable (sorted, relevant for the emergency situation, and easy to identify), and 20% of these supplies had to be destroyed by the end of 1989. Unsuitable donations caused bottlenecks in the supply chain, making storage and transportation processes more inefficient.

Donations place additional complications on the procurement process, since it is difficult to define what will come from donors and what will have to be sourced from vendors. But even if donations are not considered, the procurement process is by itself a challenging task. Supply availability is highly dependent on the location. Organizations often have a low visibility into existing inventory. Control of inventory is usually given to country offices, resulting in excess supplies in some locations and scarcity in others. The selection of suppliers during the procurement process includes not only total cost versus quality, response time, and reliability trade-offs, but also considers less measurable factors like activating local economies by choosing a local provider. Developing contracts with suppliers is difficult given the uncertainty of the type, quantity and timing of items required, and the available budget. Also, there is competition for supply sources when there are

Figure 2. Relief supplies categorization and examples.

local or international nongovernmental (non-profit) organizations (NGOs) sharing similar relief objectives, and further there is lack of coordination among them.

Challenges faced while sourcing from donors or vendors after the event occurs may affect supply availability. The shortage of supplies may cause emergency response to be ineffective and result in increased human suffering [7]. Hence it is important to develop strategies to accelerate supply response or deal with unpredictability of demand. One strategic initiative that has been recently implemented by several humanitarian organizations is the prepositioning of inventory instead of procurement after the fact. Prepositioning allows not only faster response but also better procurement planning and an improvement on distribution costs; however, it requires an additional investment before the event occurs, and funds are more difficult to obtain.

In summary, the supply process in a humanitarian supply chain is different from regular supply chains. Supply in regular supply chains follows a standardized order fulfillment process, while in the case of disasters a portion of supplies comes from voluntary donations. Also, since humanitarian supply chains are often in resource-poor environments, supply may be especially variable. Greater certainty on the supply quantity, location, and time; longer relationships with suppliers; and information about the suppliers available at the location of interest before decisions are made allow better procurement contracts for normal supply chains. Finally, when common supply deals with routine events and not a one-time disaster event, developing a procurement “expertise” is easier.

DEMAND

The customers in a disaster supply chain include the population at the affected area, as well as intermediate customers at local or global storage facilities. Their needs change significantly according to disaster types and the phases in the disaster timeline. In the predisaster phase, protection-based items

like batteries and flashlights are highly demanded both by the people and local stores for preparation, while immediately after the disaster, the high demand changes to first-response items like drugs, medicine, food, water, and shelter. Long-term recovery items like infrastructure repair and construction equipment are among the items needed during the postdisaster period.

The demand patterns are also different in each phase. The predisaster stage consists of planning processes that are mostly based on forecasts, so the demand is not certain. Once a disaster hits, demand becomes complex: high and quickly changing, but more certain based on the reported needs that are sent eventually by the assessment team in the disaster area. During the postdisaster period, demand again stabilizes and becomes more predictable with the real data from the region. The overall demand structure of disasters is complicated and challenging because of the high unpredictability of its three main dimensions: time, location, and magnitude. Also, disaster demand has other drivers related to those dimensions such as population characteristics, economy, and political conditions; these factors are also complex to formulate.

Dependency of demand in disasters on these hard-to-measure factors and its high uncertainty are the main differences from the demand in regular supply chains. Unlike logisticians in the private sector, humanitarian workers are always faced with the unknown: when, where, what, how much, where from, and how many times; in short, the basic parameters needed for an efficient supply chain setup are highly uncertain [8]. Disaster demand forecasting is also difficult due to the lack of historical data. Even though there do exist some databases from the past experiences prepared by both NGOs and governments, such as the EMDAT (Emergency Events Database) by the Center of Research on the Epidemiology of Disasters, they are occasionally inadequate because of inconsistent and/or insufficient data collection and reporting problems [9]. Additionally, disasters are unique even if they occur in exactly the same location, since other factors such as population structure or economic conditions

could have changed since the previous occurrence. Hence, historical data is not always very useful for predicting future demand.

DISASTER SUPPLY CHAINS

Supply chains link the sources of “supply” (suppliers) to the owners of “demand” (end customers). In a typical humanitarian supply chain, governments and NGOs are the primary parties involved. Governments hold the main power with the control they have over political and economical conditions and directly affect supply chain processes with their decisions. After the 2004 tsunami, for instance, the Indian government did not invite international aid agencies to participate at all in the first 60 days of the relief effort, and functioned during that period with the local sources of supplies [10]. Donors, military, and the media are the other significant players in the humanitarian supply chains.

Disaster Supply Chain Management

Supply chain management is the process of planning and controlling the operations of the supply chain by coordinating the different parties involved in the process of fulfilling customer demand efficiently.

Coordination and management of disaster supply chains have challenging problems. The supply network is huge and complicated with numerous players (donors, NGOs, government, military, and suppliers), and it is hard to coordinate all of them along with all the items that need to be delivered. Despite the different cultural, political, geographical, and historical differences among them, collaboration and specialization of the tasks between NGOs, military, government, and private business are increasingly needed in the humanitarian supply chains [8]. Despite being experienced and aware of the key points in humanitarian supply chains, people in charge of logistics and supply chain management in most NGOs or other humanitarian organizations are not often specialized in this area, and therefore they are not experts in the tools for solving the problems that might occur during the operations. There could also

be domestic barriers such as the need of excessive paper work, specific policies of the region that may cause additional delays, as well as external complications due to foreign relations.

Use of technology is essential in managing supply chain operations and maintaining coordination, but the organizations usually do not use specific software or other technology tools for supply chain management. The case study written for El Salvador earthquake in 2001 [11] focuses on coordinating the logistics and supply chain operations using a humanitarian relief supplies management software called SUMA. SUMA’s objective is “to develop a standardized methodology and operational capacity at the national or regional level to manage relief supplies and equipment efficiently” [12]. The implementation of this software allowed the identification urgent needs, helped prevent unsolicited donations that could upset the system, and created reports with centralized information to inform the population about the development of the operations, building visibility and transparency through the supply chain.

Finally, goals and performance metrics of humanitarian and regular supply chains differ notably. Unlike the humanitarian supply chains, which do not have any profit targets and rely heavily on volunteers and donors, in regular supply chains, stakeholders are the “owners” of the chain. A company has to improve its profits and aims for making more money. It is easier to prove success using profit data in private supply chains, but how to prove success is not clear for humanitarian supply chains because cash flow data may not fully explain results. Nevertheless, the numerous models based on minimizing cost (or equivalently, maximizing profit) for building efficient supply chains can be applied to the humanitarian supply chains directly or with modifications. One example is an integrated, multiobjective supply chain model that uses fill rate, cost, and flexibility as measurement factors for simultaneous strategic and operational supply chain planning [13]. Lodree and Taskin [14] work on stochastic production/inventory

control models for recovery planning, specifically for hurricanes, to determine how long to postpone decision making to optimize the trade-off between logistics cost efficiency and hurricane forecast accuracy.

Disaster Supply Chain Execution

The execution or delivery process in a supply chain consists of bringing supply and demand together. Delivery could mean different things at each disaster stage, such as setting up temporary warehouses or shelters during the preevent stage or delivering relief to affected people during the response stage.

Distribution operations within a disaster framework are very challenging. Owing to the complexity of the sourcing process and the uncertainty of demand, there could be a big gap between supply and demand in terms of mix, quantity, timing, and location, and matching them becomes a hard task [15,16]. Handling expertise becomes more challenging due to the large span of relief items and the use of ad hoc warehouses. Transportation infrastructure is highly dependent on the location; it may be damaged or disrupted and suffer from dynamically changing conditions. Additionally, communication infrastructure may be disrupted. Because of the sudden onset of most disasters, problems associated with inadequate distribution planning are common, including high expediting costs, choice of wrong transportation mode and/or provider, bottlenecks in the port of entry, incomplete execution, and so on. Hence preparation during the preevent stage is vital, and strategies such as the use of staging areas for prepositioning and distribution of relief supplies [17] help overcome the difficulties in getting the right supplies to the right people, at the right time, at the right place.

Humanitarian supply chain delivery operations may have different targets than for-profit supply chains. Usually, there is a trade-off between cost and responsiveness of the delivery process. In the case of disaster supply chains, responsiveness concerns human welfare, and it has a higher priority compared to operational cost than regular supply chains. Since every human life is equally valuable, fairness is a particularly

important criterion for disaster supply chains, and their responsiveness should not be based to the social or economical condition of the affected people.

AN ILLUSTRATIVE EXAMPLE—DEBRIS MANAGEMENT OPERATIONS

Depending on the nature and severity of the disaster, and the characteristics of the affected area, there could be massive amounts of debris. The resources required to collect the debris might be limited, debris could be blocking roads and obstructing aid supply, and some types of waste can endanger community health and safety; therefore, resources have to be allocated adequately to speed up the debris collection and disposal process, while minimizing its impact. Debris collection becomes a complex logistics issue, and a debris management plan should be developed in advance addressing each disaster stage [18]. Figure 3 shows the main elements of such a plan, based on the guidelines of the Federal Emergency Management Agency of the United States [19]. While a management plan answers the question of what to do, OR answers the question of how to do it most efficiently and effectively.

During the preevent stage, forecasts are made to predict the quantities and location of debris. Debris forecasts are used to plan for the resources, to design debris management sites for temporary storage, and to develop adequate strategies for final debris disposal. An adequate debris forecast that considers the type and extent of the potential disaster and historical data is essential for effective preparedness. During the resource planning, debris collection authorities may realize that existing forces and equipment will not be sufficient and some services must be outsourced. Choosing both the right contract (unit price, lump sum, time and materials, etc.) and the right contractor is fundamental for controlling the costs, quality, and availability of the procured services. Finally, a facility location model (see *Integrated Supply Chain Design Models*) could be used to select among potential debris management

Figure 3. Elements of Debris Collection Management Plan.

sites such that the use of these locations expedites the collection process while minimizing additional costs.

During the response stage, having access to injured people and to critical facilities such as hospitals or police stations is crucial. Roads and streets that are essential for the emergency operations might be obstructed, and debris must be removed to facilitate rescue efforts. A network model can determine how resources should be allocated and which roads should be cleared first. Such a model takes into account the priority of the facilities to be connected in order to maximize the supplied relief as well as the available quantity of workforce and equipment.

The longest phase of the debris collection process occurs during the recovery stage of a disaster, once emergency and other major routes are cleared from debris. After the disaster, community residents begin to take debris to public rights-of-way, and this debris along with what was left after the response stage has to be collected. Debris such as white goods (containing refrigerants and other regulated machine fluids) and hazardous waste has to be handled with special care because of their environmental and health safety impact. Scheduling and

routing models for the debris collection resources can be developed to minimize the impact of the remaining debris while using the available resources efficiently to reduce costs. A model of this nature assigns each resource to loading tasks at the debris sites and unloading tasks at the debris management sites. After the debris is collected, it may go through some reduce or recycle processes, and then be taken to its final destination. Deciding the best policies to follow for each debris type is not a trivial problem when different constraints such as environmental regulations, available capacities, budget, and so on, are taken into account. A mathematical model can help the decision maker to find an optimal trade-off of cost and environmental impact.

CHALLENGES AND FUTURE RESEARCH DIRECTIONS

The use of OR techniques for disaster preparedness and response can help improve the efficiency and effectiveness of processes extensively. The challenges defined in this article about the particular structure of disaster supply chains demonstrate their differences from regular supply chains. Since

disaster supply chain management is a newly emerging research area, there are many problems to be solved and new directions to be discovered for future research beyond the limited literature so far.

Most of the current research on disaster operations management focuses on the pre-event phase, which covers planning, mitigation, and preparedness processes. There is limited research in recovery planning phases. Furthermore, when a specific problem within a disaster context is modeled, the model usually focuses on one specific stage (preevent, response, postevent). However, there is an undeniable interaction between the decisions made at different stages; that is, what is done today affects what can be done tomorrow. Therefore, more comprehensive models integrating multiple disaster stages are needed.

One of the main characteristics of disaster supply chains is the presence of multiple stakeholders (NGOs, governments, local authorities, etc.). In this multifunctional environment, each of these players might have different objectives and priorities, leading to potential conflicts and inefficiencies in operations. Also, the best decision for each stakeholder alone is not the same when the entire supply chain is considered; that is, inefficiencies exist when individual incentives are not aligned. To handle the system as a whole, hierarchical planning, multiobjective models, centralized/decentralized system trade-offs, standard procedures, information sharing platforms, collaboration mechanisms, and incentive models need to be developed and analyzed.

When dealing with disasters, the human factor is always present. Even the best model that reflects the real conditions does not provide the perfect solution for disasters unless it takes human factors into account. Therefore, there is a need to incorporate behavioral aspects into the mathematical models. For example, in order to design an effective evacuation model, the model should be able to predict and incorporate the different reactions and attitudes of the people. There is a

limited amount of work connecting mathematical representation and behavioral dynamics [20], and this multidisciplinary approach has a high potential for more efficient solutions for disaster supply chains.

Finally, there is need for models that fully describe a disaster supply chain system within stochastic, dynamic, and adaptive settings. A stochastic model would be able to capture the high uncertainty in demand, supply, and delivery in these supply chains. Even though there is some work done modeling disaster- and emergency-related problems under uncertainty, many of the models in the literature are deterministic. Incorporating the dynamics of the choices made during each time period is crucial because of the strong interactions of these decisions. The proposed models should also be adaptive to incorporate new information when a change occurs. In a disaster framework, information is usually limited at the beginning, and as time passes, more and more accurate information becomes available. The model should capture and make use of the new pieces of information.

Disaster supply chain management is a rising area of OR, which has the potential to make a significant impact on the society. Defining the systems accurately and developing models that fit the structure of disasters are essential for applying OR techniques in disasters applications.

OPERATIONS RESEARCH TOOLS FOR ADDRESSING CURRENT CHALLENGES IN EMERGENCY MEDICAL SERVICES

SHANE G. HENDERSON

School of Operations Research and
Information Engineering,
Cornell University, Ithaca,
New York

The job of an emergency medical service (EMS) provider is to respond to calls for assistance, render urgent medical care at the scene of a call and then, if necessary, transport the patient to an appropriate hospital. An EMS provider must coordinate the actions of many ambulances, the staff in which may have different levels of training, to address calls of many different types. Call volumes vary significantly according to cyclical patterns on a daily, weekly, and annual basis, and calls are certainly not evenly spread over geographic regions.

EMS problems are similar to those faced by other emergency services including fire and police, although there are important differences. For a superb overview of work in these various fields to the early 1990s, see Ref. 1; and for some recent commentary, see Ref. 2. The survey [3] is a valuable reference for both operations research (OR) specialists and EMS professionals, although it is written primarily for EMS professionals. EMS problems also have some similarities with the taxi and courier industries, although the latter industries can benefit from *a priori* scheduling of a nontrivial fraction of their calls.

The focus in this article is on *operational* issues rather than *clinical* issues. Clinical issues are those issues that are essentially medical in nature, such as the difference that prompt intubation can make to patient survival rates. The clinical side is extremely active. See, for example, the *Annals of Emergency Medicine*, the *Journal of Emergency Medical Services*, or *Academic Emergency*

Medicine. These journals occasionally publish articles that focus on operational aspects.

OR has been used to assist in decision making in EMS at least since the 1960s [4]. Typical applications include the siting of new bases and staff scheduling. But there are still a host of challenges faced by EMS providers, some of which are variants of these well-known problems, while others have arisen only recently. The goal of this article is to describe some of these challenges and suggest possible avenues of (operations) research that might help address them. We will particularly emphasize system-status management (SSM) as a tool for addressing several problems at once. The article is not meant to be a state-of-the-art survey, but rather a “call to arms.” To absorb the entire article, the reader should have a background in the tools of OR, say at the undergraduate or masters level, but much of the discussion should be accessible without this background.

This is one of two articles that deal with EMS. In the other article titled *Emergency Medical Service Systems that Improve Patient Survivability*, the goal is to provide an overview of next-generation EMS design that helps address the problems faced today. In contrast, we start with the problems of today, indicate potential solution approaches, and go into depth on one approach (SSM) that is already in use.

The good news for an operations researcher looking at EMS problems is that the area is data-rich. Computer-aided dispatch (CAD) systems have been in place in many locations for over a decade, and so in large centers it is invariably the case that data is available on every call. This is not necessarily the case in small centers, however. The amount of data varies, but there is usually at least three years’ data available as of 2008, and often much more—even decades in some places. Time stamps are logged for each call, including the time the call was received, the time the call was assigned to an ambulance, the time the ambulance was en route to the call, and so forth. Some of these time

stamps are logged manually by ambulance officers, while others are logged automatically by the CAD system, so the quality of the time stamps varies (people occasionally forget). A key component to planning systems is travel-time information, including time-dependent travel times or speeds on road networks. This sort of data is often available from town planning departments, but is usually intended for long-term planning questions, so often needs editing before it is suitable for EMS applications. A potential source of travel-time data is automatic vehicle location (AVL) data, which is becoming much more widely available as global positioning system (GPS) units on ambulances become standard. AVL data gives the location of ambulances as recorded by a GPS unit at regular intervals of time. GPS readings vary in quality depending on how accessible the GPS satellites are. For example, GPS readings often degrade when ambulances are in tunnels or in the urban canyons that are typical of the centers of large cities, so even this data source varies in quality.

The pressing need for efficiencies in EMS systems, together with the availability of large amounts of data, suggests that quantitative OR methods, together with appropriate statistical methodology, should be well positioned to strengthen an already well-established presence in EMS.

AN OVERVIEW OF EMERGENCY MEDICAL SERVICE CHALLENGES

Measuring Performance

EMS systems are designed to help reduce morbidity and mortality by quickly and safely responding to calls, providing emergency medical assistance at the scene, and transporting those patients who require further treatment to an appropriate hospital. As with many decision-making questions in health care, it is difficult to quantify the medical impact of changes. The traditional approach is to measure performance through response times. The response time for a call is the elapsed time from when the call is received to when an ambulance arrives at the scene. Performance is then measured as the

fraction of calls received that have response times of x minutes or less, where x is usually 8 or so; see Ref. 5 for historical notes and discussion from a practical perspective. Let us call this performance measure the response time threshold fraction (RTTF). RTTFs are often reported separately for different regions and different time intervals, so that a picture of performance in space and time can be obtained.

The RTTF is easily explained, easily measured, and unambiguous. It can also be computed using existing methodologies including simulation and hypercube methods. (See Ref. 6 for an overview of simulation in EMS and Refs 7–9 for how to do this using the hypercube method.) These are important advantages that help to explain why RTTF is so prevalent in the industry. RTTF has its origins in cardiac survival studies, where survival rates are linked to response times. But it is also somewhat arbitrary. The threshold of 8 min is chosen from the survival probability versus response time curve, and is often adjusted depending on whether one is in a rural setting (larger values are used) or a metropolitan area. It is also highly city dependent, with values 8, 9, 10, and 12 being common choices. Different thresholds are used for different types of calls, since some calls have lower priorities than others and so naturally receive slower response times.

For all of these reasons, there is great interest in finding better performance measures than RTTF. One approach is to use a utility function u so that a call with response time t receives a utility or “score” $u(t)$, and the goal is to maximize the average utility over all calls. RTTF is actually a special case where u only takes values 0 and 1. The utility approach is a central theme in both (also see *Emergency Medical Service Systems that Improve Patient Survivability*) [10], where the utility function adopted is again based on cardiac studies. Of course, there are other types of calls including, for example, trauma calls, so interpretation of the utility can be difficult, even when it is specialized to different types of calls. As another example of the difficulty in coming to agreement on utilities, many cardiac patients wait for some

time before calling EMS, so a few minutes difference in response time is somewhat immaterial when there has already been a delay of up to a few hours. Nevertheless, the idea of attaching utilities to calls and measuring average utility is important. For example, a key observation in Ref. 10 is that solutions to ambulance deployment problems obtained using RTTF can perform very poorly when measured in terms of average utility.

Perhaps, we should continue to err on the side of simplicity and simply measure performance in terms of *average* response times instead of RTTFs or more complex measures. See article titled *Emergency Medical Service Systems that Improve Patient Survivability* for some discussion of this question.

Some EMS providers additionally measure performance in other ways. For example, one approach to ambulance deployment used in Edmonton, Alberta, is to specify, for each number of available ambulances, a set of locations that they should occupy. When ambulances are appropriately positioned, the service is said to be “in compliance,” and performance is measured by the fraction of time the system is in compliance. One would expect that RTTFs are also tracked.

Delays at, and Diversion from, Emergency Departments

The time required to transfer a patient from an ambulance to an accepting emergency department varies greatly depending on the medical needs and priority of a patient and how busy the emergency department is. Typical desired transfer times are on the order of 15 min, but in many cases can be as large as 1 h or more. This places tremendous pressure on EMS organizations because it dramatically increases—even doubles—the time required to handle each call. Another serious problem is known as *ambulance diversion*, which occurs when an emergency department notifies dispatchers that it will temporarily not accept patients from ambulances. The resulting patient transport times are increased because ambulances are forced to go elsewhere, again impacting ambulance utilization.

Both transfer delays and diversion can have serious medical consequences. A statistical study [11] links ambulance diversion to increased death rates from heart attacks. The problem may be even more serious than this paper suggests, since transfer delays can be much larger than the additional driving time associated with diversion.

What can be done to reduce the impact of delays and diversion?

One approach that has been tried is to place an EMS paramedic at each receiving hospital. The paramedic receives patients from arriving ambulances and subsequently transfers those patients to the emergency department when possible. When not busy with this function, the paramedic can assist in the emergency department. One can think of the paramedic as a buffer (in the sense of manufacturing) between arriving ambulances and the emergency department. In one case, this was observed to work well for about one week, until the hospital realized it could use the EMS paramedic for its own ends, and patient transfer delays returned.

This points to a key problem in that hospitals and EMS systems are usually operated as separate organizations. The incentives that are in place for both organizations are not geared toward inducing cooperative behavior in the emergency department where these organizations interface.

There are at least three possible solutions to this problem.

The first, and most obvious, potential solution is to immediately conclude that hospitals need more resources to cope with the flows of patients entering their emergency departments. But as noted in several places [12, 13] any problem may lie downstream from the emergency department, in hospital wards that need to free capacity to allow emergency department patients to be transferred. It may also be the case that the systems in place in hospitals can be streamlined to make it easier for emergency department staff to keep pace with patient flows and reduce the need for ambulance delays and diversion. This is a key place where OR can help.

The second potential solution is to adopt some form of “regionalization,” as is currently under way in a number of provinces in

Canada to varying degrees. Here the hospital and pre-hospital organizations are placed under a single umbrella organization, with the goal that the pre-hospital and hospital organization are now a single organization and therefore will “pull in the same direction.” It is not yet clear whether this step will help though, because the size of the pre-hospital and hospital organizations makes it difficult to maintain a “systems view” of operations, and it is very likely that a hierarchical organization will result, with EMS on one branch and emergency departments on another, perhaps leading to the same situation we have now. This is not a foregone conclusion of course, but it is one possible outcome.

The third potential solution is to redesign the incentive schemes for both EMS and emergency departments, that is, change the performance measures that are used to report their performance, along with how those performance measures are written into contracts. Perhaps by aligning the incentive schemes using the game-theoretic field of mechanism design, one can design contracts that lead to outcomes that are simultaneously of high quality for patients, EMS providers, and emergency departments.

Increasing Traffic Congestion

The high-profile aspect of traffic congestion is large-scale traffic jams. But traffic congestion can also mean large traffic flows on a daily basis, and therefore slow travel on routes that were never intended to handle the volumes that they receive. Even when ambulances travel with lights and sirens, it can take time for drivers to react and clear a path for an ambulance. Furthermore, ambulances spend significantly more time traveling at regular traffic speeds than at lights and sirens speeds, in which case they are slowed by traffic congestion, thereby increasing the load on ambulances for the same call volume. This, in turn, translates into increased response times due to unavailability of the closest appropriate ambulance.

So what can EMS providers do about this problem?

Rather than maintain ambulance bases with three or more ambulances at a base,

many EMS providers now spread their available ambulances around the city. This is sometimes known as *parking on street corners*. Crews are asked to sit in their ambulances in parking areas, waiting for calls. The particular locations are chosen depending on time-dependent demand and travel speeds, and various methods are available for such planning [14]. This has the effect of reducing the driving distance to calls, and therefore can improve response times. It also creates the need for real-time ambulance location and relocation. To see why, picture a city with evenly spread ambulances. When a call comes in, one of those ambulances “disappears” from the picture, leaving a potentially large “gap” in coverage. It may then be advantageous to move one or more nearby ambulances to reduce the size of this gap. This process of using real-time information to relocate available ambulances is known as *system-status management*, and we will discuss it in depth later in this article. It is worth noting that under a system where multiple ambulances are stationed at a single base, only occasionally are all ambulances at the base busy with calls, so gaps in coverage do not open up as frequently. However, because of the clumping of ambulances at bases, the distance between available ambulances is typically large, and this translates into large response times.

The use of SSM methods makes having accurate travel-time or speed information more important than ever. As mentioned earlier, currently available speed information on road networks is usually not very accurate, so one would like to “tune” the speeds, probably using AVL data. But how should this be done, given that the data consists of noisy observations of ambulance locations at discrete points in time, so one is uncertain even about the exact route that an ambulance has taken? The field of map matching [15,16] is undoubtedly an important tool that can perhaps be combined with carefully designed statistical methods to update modeled travel speeds. See Budge *et al.* [17] for a recent statistical study of travel times that models travel times as random, and Henderson and Budge *et al.* [18,19] for the consequences of travel times being random.

Vehicle Mix Questions

Should one's ambulance fleet consist of advanced life support (ALS) vehicles only, or a mix of ALS and basic life support (BLS) vehicles? To understand the distinction, note that ambulance staff can have a variety of levels of training. *Ambulance officers* (also called *emergency medical technicians*) typically have on the order of several weeks of training and are highly adept first responders. However, they cannot deliver the higher level of care needed on a significant fraction of calls that a *paramedic* can provide (e.g., administer drugs) due to a much higher level of training. ALS vehicles have a paramedic on board, while BLS vehicles do not.

Most cities have a mix of ALS and BLS vehicles, although some authors strongly advocate an ALS-only system [20]. It is cheaper to run a BLS ambulance than an ALS ambulance, so for a given budget one can operate more vehicles in a mixed fleet than in an ALS-only fleet. With a mixed fleet, one sends BLS vehicles to calls where paramedic-level attention is not needed. However, this requires that dispatchers make a determination at the time of receiving a call about which type of vehicle to send, thereby inflating the time required before dispatching a vehicle, and creating the possibility of sending the wrong vehicle, leading to additional delays before a high level of care can be provided. The trade-offs between ALS-only fleets or a mixed fleet are therefore complex, and it is not clear which approach is better in a given situation. OR tools can help quantify the trade-off to assist in making a determination. For example, simulation was used in Ref. 6 to model the trade-offs between sending a vehicle to a call based on minimal information from a caller, as opposed to obtaining more information from the caller before dispatching (ProQA). Using ProQA ensures a better match of vehicle type to the call, but slows down dispatch times, thereby inflating response times.

The ALS/BLS mix is just one example of a number of vehicle mix questions. For example, some EMS organizations use vehicles staffed by a single paramedic, which can rapidly respond to calls but cannot transport patients. How many such vehicles should be

employed? Should scheduled patient transports be performed by emergency vehicles or by a fleet dedicated to the task? And to what extent should EMS organizations employ helicopters?

Increasing Call Volumes

Virtually all EMS providers are seeing their call volumes increase over time. This increase is probably a consequence of many factors, including population increase, demographic changes (which are strong predictors of call volumes [21,22]), and what the general public perceives as the threshold for calling an ambulance. This obviously poses challenges for an EMS provider whose budget is often constrained.

Using careful dispatch strategies can help. For example, it has been known for some time [23] that sending the closest available vehicle is not necessarily optimal, because it can lead to imbalances in workload and therefore inflated response times. Nevertheless, most dispatchers follow either exactly this policy or one very close to it, partly because of the danger of litigation in the event of an unfortunate outcome, but also partly because there is a lack of decision support systems that can help with this decision. What do optimal dispatching policies look like and how can they be deployed in a dispatcher-friendly manner?

Another question we must ask ourselves is whether all of the incoming calls actually *need* EMS response. During the September 11 attacks in New York City, some emergency departments noted a considerable *drop* in patient arrivals that was not due to a lack of ambulances. It appears that the general public felt that their problems were outweighed by the needs of potential casualties from the World Trade Center and did not call for help. In many cases, no doubt, they should still have called for help, but it does make one wonder how much EMS and emergency room demand could be mitigated using other strategies. Is there a way to shape demand, perhaps through public education schemes? Would such schemes lead to better outcomes in the sense of overall public health, or would such schemes reduce EMS call volumes at the expense of public health?

Yet another approach to dealing with increasing call volumes is to attempt to obtain better performance from the resources at one's disposal. One such method that can help immediately, and that is already in use, is system status management, and this is the subject of the remainder of this article.

EXISTING APPROACHES TO SYSTEM-STATUS MANAGEMENT

Many ambulance organizations are moving away from the model where ambulances are stationed in twos and threes at bases, instead preferring to spread the vehicles out over the city in an attempt to reduce the travel distance to calls. When a call is received and an ambulance is dispatched to the call, a "hole" is left in the coverage of the city. Should the nearby vehicles be rearranged? If so, how? Any method that gives a strategy for performing such rearrangements is known as *system-status management*, or by one of the synonyms move up, redeployment, dynamic relocation, or dynamic positioning.

In order to implement SSM, dispatchers need to be aware of the location and status of the ambulance fleet. This is not difficult for EMS organizations that have installed GPS units on all vehicles and where crews send updates on their status to the dispatch center. Indeed, virtually all large EMS organizations have adopted these practices.

Another key issue is ambulance crew receptiveness to SSM. Many implementations encounter some resistance from crews and perhaps with good reason. Ambulance crews have a stressful job that also requires them to work in shifts. On top of that, a poorly implemented SSM approach may lead to crews spending almost the entirety of their shift driving between locations to fill holes in coverage, or parked in some undesirable location that is far less comfortable than any ambulance base. The crews do not see the "birds-eye view" that leads to these redeployments, and so the trips can seem pointless to them. However, if implemented with care, SSM can obtain material improvements in response time with only modest disruption to crews.

We now describe specific methods for implementing SSM.

Manual Search and Selection

Suppose a dispatcher is considering redeploying a specific ambulance to one of several potential locations. Experience often guides the selection of a specific location. "What-if" tools can also help. For example, one approach is to assume that all other vehicles will not change status or location in the short term, and then consider the candidate locations, one at a time. As long as the number of candidate locations is small, it is typically a simple matter to recompute some measure of quality (usually "coverage," where coverage means the fraction of future demand that can be reached within some time threshold from the candidate locations) at each candidate location and select the one that is best. Graphical tools that display coverage, for example, by coloring locations in a map according to projected response times, can also help. This is the basic idea behind simple implementations of SSM. Such implementations are easy to understand by dispatchers, but they also have some important shortcomings.

1. It can be difficult to gain a picture of both call density by location and coverage in graphical displays. Therefore, dispatchers need experience to help in determining which vehicle relocations might prove effective.
2. It is difficult to consider all possibilities when simultaneously considering moving two or more vehicles because of the combinatorial increase in the number of candidate locations that need to be considered.
3. The status and location of ambulances is constantly in flux, so decisions based on such static models can miss the fact that the situation may look very different by the time any relocations have been completed.
4. In busy systems, it is quite possible that vehicles on their way to a new location may be dispatched to a call before they reach their intended destinations,

calling into question the basis for the relocation decision.

5. It is difficult to get a sense of which relocations are the most important ones in terms of reducing response times, which is important when one wishes to limit relocations to avoid frustrating crews.

Real-Time Optimization

Several of the disadvantages of the real-time manual approach discussed above motivate an automated approach. All such searches rate candidate solutions using some measure of quality, which is usually coverage, as defined above, although other measures have been used [24]. Exhaustive searches can work quite well when the number of potential relocations is small, but they can quickly become overwhelmed when multiple ambulance moves are simultaneously considered. It is then that optimization-based methods become the preferred approach.

The first optimization-based method was developed by Kolesar and Walker in the context of fire-fighting operations [25]. It involved solving, in real time, three integer programs using heuristics. Unfortunately, one cannot just “cut and paste” this approach into the EMS setting, because there are some important differences in the way fire services and EMS services operate. The key differences are that (i) fire companies have much lower utilization than EMS (to ensure that they can respond rapidly to major incidents), and (ii) fire companies can be engaged at a structure fire for 8 h or more, whereas it is unusual for an ambulance to be engaged in a single call for more than 2 h. These differences mean that it is reasonable to assume that the dominant system conditions will not change during a fire company deployment (call), while, as we argue below, in the EMS setting such an assumption is problematic.

A real-time optimization approach was developed in Ref. 26. The integer programming formulation ensures appropriate coverage of various locations, that vehicles are not relocated too often and that vehicles do not take too many “round trips.” A tabu-search

heuristic on a parallel computing platform was used to solve the model. Similar formulations have been adopted in some commercial systems.

Offline Optimization

An alternative to the methods above is to develop a lookup table which gives, for each number of available ambulances, the set of locations where available ambulances should be positioned. Dispatchers then attempt to direct the ambulances to occupy those locations with as little disruption to crews as possible. Lookup tables can be time-dependent to reflect time-dependent travel speeds and demand patterns, and are compact and easily understood. But how can they be constructed?

Here, one can exploit the large amount of available research on identifying optimal base locations in the *static* version of ambulance deployment where ambulances always return to their preassigned bases when free. Integer-programming methods (see Ref. 27 for a recent survey) are available for selecting ambulance locations for a given number of ambulances. One can solve one such optimization problem for each number of available ambulances. A difficulty here is that there is no attempt to ensure consistency between the set of locations chosen for n available ambulances, and those chosen for $n + 1$ available ambulances. This can lead to many redeployments, which should be avoidable. A partial solution is to require that the redeployment locations be *nested* in the sense that the set of locations chosen for n ambulances be a subset of those chosen for $n + 1$ ambulances, for each $n = 1, 2, \dots, N - 1$, where N is the total number of ambulances in the fleet [28]. These nesting constraints can be satisfied by solving a single, large integer program that simultaneously finds the optimal locations for all $n = 1, 2, \dots, N - 1$, and includes explicit constraints that enforce the nesting.

This method is a highly appealing and important option for SSM implementation, but it does possess some disadvantages. In particular, Issues 3, 4, and 5 identified as difficulties for manual selection are also important difficulties for this approach.

Stochastic Dynamic Programming

The most important issues with the methods we have discussed thus far are that (i) they are based on the assumption that vehicles are exactly at the desired locations at all times, and (ii) they cannot give a clear sense of the importance of particular redeployments. Both of these issues can be addressed using stochastic dynamic programming (DP) models.

DP models were first introduced for this problem in work by Berman and co-authors in Refs 29–33. DP is certainly a very natural framework to employ, since it is the study of problems where decisions must be made over time in the presence of uncertainty, which exactly describes our problem. To apply DP, one tracks the locations and status of all ambulances over time. At any decision point, one defines a set of actions (potential redeployment decisions) that might be taken. The actions are of the form “send ambulance x to location y .” The DP is designed to discover a *value function* V that gives the quality of a particular configuration of ambulances at a particular time. The function V maps the system states (ambulance locations and status, and time) to a measure of the quality of the configuration, which can be interpreted as the expected performance of the system (e.g., number of calls answered on time) starting from that particular state. Once one obtains the value function V^* associated with an optimal policy, it can be used to determine the optimal decision at any stage by implementing the associated greedy policy: At each decision point, one selects the action that maximizes the expected value of the immediate reward plus “downstream” rewards. See Puterman [34] for a comprehensive introduction to DP and full discussion of these concepts.

Recently, Zhang *et al.* [35] have revisited the use of DP for ambulance relocation, establishing a number of results that help build intuition for what optimal policies look like. Their results show that one should send vehicles to one of several distinguished locations, where the set of locations depends on the arrival rate of calls. Furthermore, they show numerically that the heavier the load of calls

on the system, the less effective SSM can be relative to a static policy.

In the papers mentioned above, the approach is to obtain the optimal value function V^* by storing a value for *every possible state* and applying standard DP techniques. This necessitates keeping the number of states small, which means that only very small examples can be treated. Therefore, the models addressed in this work are somewhat stylized. The results are important in that they help build our understanding of when SSM can be effective and what effective policies look like, but the approach cannot be applied directly to realistic-sized systems. To enable the leap to realistic-sized systems, a different approach to representing the value function is needed, which brings us to the subject of approximate dynamic programming.

APPROXIMATE DYNAMIC PROGRAMMING FOR SYSTEM-STATUS MANAGEMENT

Approximate dynamic programming (ADP) is a general-purpose suite of tools for solving problems where successive decisions must be made over time under uncertainty. Essentially, ADP involves an implementation of dynamic programming where one stores an *approximation* for the value function, instead of the value function itself. This allows one to tackle problems that would be impossible with exact DP owing to the huge (often infinite) state space involved. The catch is that one cannot, in general, expect ADP to find an *optimal* policy. The goal, instead, is to find a *high-quality* policy in a computationally tractable manner.

We will sketch the key ideas behind an ADP approach to SSM developed in Ref. 36 and further explored and improved in Ref. 37. We will refer to this approach as *our* approach because the present author was one of the authors of this work. The goal is to minimize the fraction of calls received that have a response time that exceeds a given threshold. We refer to such calls as *lost* or *missed*. The specific version of ADP we use is an adaptation of a generic approach for ADP that was initially described in Ref. 38 and involves a mix of simulation and regression.

Let V denote an approximation to the optimal value function. We will explain where the approximation comes from shortly, but for now assume that it is given. Associated with V is a policy, known as the *greedy policy* with respect to V , that works as follows. At each time point t at which a decision is required, let s denote the current state of the real system, which is essentially all of the information that dispatchers have at their disposal at time t . Therefore, s includes information on the location and status of all ambulances, including the time that each ambulance has been at its location at time t . It also includes information on any queued calls. It does not include information on future events such as might be obtained from an event list in a simulation, for example, the time remaining until an ambulance completes a hospital transfer in progress. One then considers each possible *action* in turn, where each action corresponds to a request for one or more ambulances to redeploy to specific locations. As a consequence of each action, the specified ambulances will begin to deploy to the new locations, but do not necessarily reach those locations before the situation changes. For each action a , we let $S(a)$ denote the random system state corresponding to the new situation at the time of the next system event, which could be an ambulance arriving at the scene of a call, a new call arriving, and so on. Also, let $C(a)$ be the immediate cost incurred by this action, which in our case is either 0 (no missed calls) or 1 (one missed call). We then compute or approximate $E[C(a) + V(S(a))]$, and choose the action that minimizes this quantity as our decision at time t . (The expectation is computed *conditional* on the system state at time t .) We then continue the simulation to the next decision point, at which time the process above is repeated.

We cannot compute the required conditional expectation analytically, and instead use a small number of simulations to obtain a Monte Carlo estimate of it for each action that is considered. We refer to this calculation as a *micro simulation*, because each replication of a micro simulation involves simulating from the current system state forward in time for at most a few minutes of simulated time, and

this can be accomplished with a very small amount of computation. In our implementation, the micro simulations for all potential actions take a fraction of a second. Furthermore, these micro simulations are only necessary when we make a relocation decision, and then only from the current state of the system, so they represent a minor computational overhead. The Monte Carlo error we incur means that we will occasionally take an action that does not minimize the true expectation. However, this will typically occur when the suboptimal action we choose has a value that is close to that of the optimal action, so we do not expect that this effect will cause practical problems, provided that the number of micro simulations is reasonable.

To summarize thus far, for a given function V there is an associated greedy policy that we can approximate using micro simulations, and this can be implemented in real time provided that one has a simulation model of the system along with the ability to observe the state of the system in real time.

So, where does the function V come from? We use a linear combination of prespecified basis functions $V_1, V_2, \dots, V_n$, that is, for each state s ,

$$V(s) = a_1 V_1(s) + a_2 V_2(s) + \dots + a_n V_n(s),$$

for some coefficients $a_1, a_2, \dots, a_n$. The basis functions are chosen heuristically to reflect characteristics or features of the state s that are thought to be important in determining a policy. In the present case, after experimentation with potentially useful functions we settled on $n = 6$ functions as follows:

- V_1 A constant.
- V_2 The number of queued calls that will definitely not be reached within the time threshold.
- V_3 The arrival rate of calls to areas that cannot be reached by any available ambulance.
- V_4 The arrival rate of calls to areas that can be reached by an available ambulance but will likely be missed because of congestion. Here we measure the loss rate of calls as the product of two terms, the first being

the arrival rate, and the second being the loss probability as measured by the Erlang loss function.

- V_5 A version of V_3 where the ambulances are assumed to have reached their destinations if en route somewhere, and where presently stationary ambulances remain where they are.
- V_6 A version of V_4 that is modified as in V_5 above.

Why did we choose these functions? The Erlang loss function was helpful in choosing static locations for ambulances [39] so it seems reasonable to include it, and SSM is designed to help in the short run—say over the next hour or so—so using versions of the basis functions associated with predicted ambulance locations on that timescale seems reasonable. But there is plenty of room for argument and art in this selection, and we do not claim that this set of functions is the best possible. Much more remains to be done in basis function selection.

Given a set of basis functions, the problem then reduces to determining the coefficients $a_i, i = 1, 2, \dots, n$. There are a variety of methods for doing this. We use regression as follows. The state s also includes the time t at which the state is observed. The function value $V(s)$ then represents the expected cost (number of missed calls) observed starting from state s at time t through to the end of the simulation horizon. (We use two weeks for the simulation horizon.) In implementing this algorithm, we have found it necessary to *discount* the costs in time. This is purely a computational device that helps ensure convergence; see Maxwell *et al.* [37] for more discussion on why this is needed and why it works. (A similar trick was employed in a different setting in Ref. 40.) So the function value $V(s)$ actually represents the expected *discounted* number of missed calls from the time t until the end of the simulation horizon. The simulation provides *observations* of the discounted number of calls till the end of the horizon. So we can use linear regression to try to align $V(s)$ with these observations.

The result of the linear regression is a set of coefficients $a_1, a_2, \dots, a_n$, which determine a new value function $\tilde{V}$. We can then iterate this process, with the next iteration simulating the greedy policy with respect to $\tilde{V}$ instead of V . After a modest number of iterations (usually less than 20 or so), we terminate the process, and select what appears to be the best policy (i.e., set of coefficients) seen thus far.

Figure 1 gives an example of the results of such a training session for data from Edmonton, Alberta. The data were modified prior to use to protect the confidentiality of Edmonton EMS performance. Here, the vertical axis plots the estimated *undiscounted* percentage of missed calls. The apparent-best policy arises after three iterations. There are two reasons why this is the *apparent* rather than necessarily the *actual* best policy. First, at each point we run a simulation to estimate the performance of the given policy. Therefore, there is simulation error in the estimates of performance. Second, even though each point gives an unbiased estimate of the performance of the corresponding policy, when we focus in on the point with the lowest function value in the plot, we are biased toward observing a point where the estimated cost is lower than the true cost, that is, the estimated cost associated with the best observed policy is biased low. If we perform an independent simulation of the estimated-best policy, we obtain an unbiased estimate of its performance, which in the case of the observed best policy in Fig. 1 gave an estimated performance of $25.4 \pm 0.1\%$. By way of comparison, the static policy (where ambulances return to preassigned bases after completing each call) misses $29.5 \pm 0.1\%$ of calls.

The results of Fig. 1 are based on policies that only consider an ambulance for redeployment when it is completing a call either at scene or at a hospital. This is appealing because it ensures that crews are not overly disrupted by excessive redeployments. However, it is possible to obtain even greater improvements in performance by considering additional redeployments. In Ref. 37, approximately an additional 3% of calls are not missed over and above the

Figure 1. An example of the training process of ADP using representative data from Edmonton, Alberta.

completing-calls-only redeployment policy when additional redeployments are considered at regular intervals.

One might reasonably ask whether ADP identifies the optimal choice of coefficients $a_1, a_2, \dots, a_n$. As mentioned earlier, the algorithm discussed above is not designed to converge to any particular set of coefficients. This is because the computational burden in training is great, so we cannot simulate a

large number of policies, which is essential if we wish to design a converging algorithm. Instead we focus on exploring the coefficient space for a highly effective policy.

The natural question to ask then is how the policy identified by ADP ranks amongst the potential policies. In Fig. 2, we give a histogram of the performances of the top-performing policies amongst 1000 policies. These 1000 policies were selected uniformly

Figure 2. Histogram showing the estimated performance of a number of policies using representative data from Edmonton, Alberta.

at random from a cube surrounding the final recommended coefficient vector a with side lengths chosen to be commensurate with the variation in the coefficients seen during the course of the ADP iterations. We see that the performance of the optimal ADP policy is very close to the best policy seen. It may even be optimal, because we again obtain bias when we focus in on the policies appearing at the extreme left of the histogram. There are no theoretical guarantees that the ADP policy would do so well, and so it may be necessary to apply a separate optimization procedure after the ADP search to refine the coefficients. We are considering this step in current research.

CONCLUSION

EMS providers face significant challenges that, in the long run, could be addressed by a variety of remedies that involve OR methodologies. We have suggested some such remedies, but they are a long way from being developed, much less implemented. SSM can help essentially immediately with many of the difficulties faced by EMS practitioners, but it needs to be implemented carefully to fully realize the potential benefits in response times while not unduly inconveniencing crews. Existing implementations vary in quality, which has led to the technique receiving a bad name with crews.

Offline and on-line optimization implementations of SSM probably represent the current “best practice” in the area, with offline optimization perhaps being more transparent and accepted by dispatchers than the on-line approach. We have explained in broad terms how these methods work. We have also sketched the main ideas behind an approach to SSM based on ADP. This new approach is already competitive with the existing optimization-based methods, and has a number of advantages over the existing methods. It is not quite ready for commercial implementation, but is certainly close to that point.

All of the methods for SSM rely on quality estimates of call arrival rates broken down by time and location. Our ability to obtain

quality estimates of these quantities lags our ability to exploit those estimates in OR models. So, while there are many potential research directions described in this article, perhaps the most pressing one is the need to expand existing efforts [41], in statistical analysis of EMS data.

OPTIMAL MONITORING STRATEGIES

IGOR KABASHKIN
Transport and Telecommunication
Institute, Riga, Latvia

TYPES OF MONITORING MISSIONS

To operate and support a system, different types of monitoring activities must be supported. Within the frame of reliability study these activities bring into correlation with diagnostic missions. The main tasks of these diagnostic missions are as follows [1]: verification of operational readiness, fault detection and characterization, fault isolation, diagnosis and repair, and other maintenance actions.

Verification of Operational Readiness

The *verification of operational readiness* is the process that verifies to the operators of a system the system's capability to meet the requirements of their operational mission. This process typically begins with system power-on and ends with the operator's assurance that the system is operable. Intermediate steps consist of a number of off-line diagnostics that run as expeditiously as possible with minimal operator involvement. These diagnostics may not be comprehensive in that they may not isolate failures, but they are complete in that all operational data and functional paths are verified.

Fault Detection and Characterization

The system commences operation after operational readiness has been achieved. *Fault detection and characterization* is an ongoing diagnostic activity to detect possible faults in the functioning system. The goal is to detect the presence of faults and to characterize their effects so that the operator can determine if the mission is affected. If the mission is affected, the system may

continue to operate in a degraded mode or it may be declared inoperable. If the system has failed, the operator executes a fault isolation and repair process to restore the system to operation.

Fault Isolation

Fault isolation is the next logical step in the fault detection and characterization process. The goal of fault isolation is to locate the failure within a single or small group of replaceable items, which if replaced, restores the system to operation. Diagnostic hardware and software may be aided by historical data and procedural activities to narrow the field of possible failure sources and focus on the diagnosis and repair activities. The correlation between the faults and the item or items that have failed can be very complex.

Diagnosis and Repair

After a failed item has been isolated, removed from the system, and replaced, it must be evaluated for repairability, repaired, or discarded if it is not repairable, and the repair verified for correct operation. The first and last of these steps are performed by the comprehensive tests available in the integrated diagnostics environment. In case these integrated diagnostics are insufficient to isolate the failure to a repairable unit (as opposed to a replaceable unit), an additional manual or automated test equipment (ATE) and custom diagnostics are employed. Manual, ATE, or custom diagnostic activities typically take place in either intermediate or depot maintenance support facilities.

Other Maintenance Actions

Systems will typically need *other maintenance actions* that must take place either periodically or on an event-driven basis. These activities are most likely associated with installation, configuration, or reconfiguration tasks, or are associated with ongoing calibration and alignment activities.

Figure 1. The structure of functional diagnostic system.

TECHNICAL REALIZATION OF DIAGNOSTIC STRATEGIES

There are two main types of diagnostic systems:

- functional diagnostics,
- test diagnostics.

The structure of a *functional diagnostic system* is shown on Fig. 1. An object of monitoring is operated in standard condition with real input signal X , real output signal Y , and in some cases input signal X is received by diagnostics equipment. The result of the diagnosis is formulated according to the analysis of X and Y signals.

The advantage of this type of diagnostic structure is the possibility to use a real operating signal without interruption of work for monitoring of an object.

The weakness of a functional diagnostic system is the impossibility of using special test signals with special parameters for more effective diagnosis.

The structure of a *test diagnostic system* is shown in Fig. 2. The object has two states switching through the commutator with two positions: “1”—normal operation, “2”—test operation. In the test status a special test signal from test generator comes to the monitoring object. Diagnostic equipment generates result of diagnosis based on object reaction.

The advantage and weakness of test diagnostic system are contrary to that of the functional diagnostic system, that is, the possibility to use a test signal with special parameters and the necessity to switch off the object from normal operation during the monitoring process.

OPTIMIZING MONITORING STRATEGIES

Monitoring strategy optimization requires the following questions to be asked:

- What are the goals for which test strategies are being optimized?
- How can the degree of optimization be assessed?
- What can be done to optimize a test strategy?
- How do diagnostic tools help perform optimization?

Monitoring strategy optimization is achieved by focusing on the overall “diagnosability” of a system or device during development. In the most limited sense, test strategy optimization refers to ensuring that tests are performed in an order that best serves development and maintenance goals. In a broader sense, optimization may encompass not only the ordering of tests, but also the enhancement of the hardware’s inherent capacity to facilitate and support effective diagnostics [2].

Optimization can serve a number of goals, including reducing cost of ownership, improved availability/readiness, reducing support environment requirements, and greater safety.

Optimization with multiple goals can be at cross-purposes. For example, improving availability may result in increased life cycle cost. Finding solutions that satisfy multiple goals can be achieved incrementally by iteratively improving diagnostic capability. The most out-of-range goals are used to provide limits to drive new cases for any iteration, thereby converging on a solution.

The degree to which case studies help to meet goals is often determined by examining familiar testability, reliability, and maintainability measures, such as fault detection/fault isolation levels, system mean time between failures (MTBF), mean cost/time to repair, likelihood of critical events, and inherent availability.

While diagnostic optimization may lead to more fundamental design changes (test point placement, partitioning, etc.), development costs can sometimes be reduced by first

Figure 2. The structure of test diagnostic system.

focusing on changes to testing, such as refining test selection/ordering criteria, additional test procedures (automated or otherwise), and changing test implementation.

It is important to recognize when changes to testing result in diminishing returns—an indication that design changes should be considered, or that the proposed changes to testing are ineffective. More sophisticated testing can involve greater development costs, often overriding any benefits, which lead to its consideration. Similar changes made earlier in the design’s development, however, can achieve much of the same optimization at a substantially reduced cost. Optimization is about finding the balance between seemingly competing criteria.

A robust engineering environment requires a powerful diagnostics assessment and optimization tool. Considering properly, the

trade-offs between design changes and testing, further requires a tool that incorporates systems engineering methodology.

CASE STUDIES

Optimal Monitoring of the System with Continuous Operation for Maximum Availability

Every component, equipment, or system has an intrinsic design capability (Fig. 3). The demand or the expected value may be below this level.

Over time the curve of capability will decrease due to fouling, wear, fatigue, or chemical attack. When this happens some maintenance has to be done to bring the capability up to the acceptable design level.

Figure 3. Effect of demand fluctuations on maintenance timing.

Unfortunately, not all components of the system have the built-in test equipment. In this case periodical test actions are required.

Markov's state transition diagram for such a system is shown in Fig. 4, where

- $\lambda = 1/T_0$ = failure rate of the system with MTBF T_0 ,
- $\mu = 1/T_R$ = repair rate with mean time to repeat T_R
- $T_m = 1/\lambda_m$ = mean of exponentially distributed monitoring times with parameter μ_m
- $\tau_m = 1/\mu_m$ = mean of exponentially distributed duration of monitoring with parameter μ_m ,
- $0 \leq a \leq 1$ = testing part of monitoring system (with the built-in test equipment).

The behavior of the examined system is described by the state transitions (Fig. 4): H_0 —state in which system is operating and available for use; H_1 —failure is in the part of the system with monitoring of the built-in test equipment; H_2 —failure is in the non-monitoring part of the system; H_3 —failure in the nontested part of the equipment is being repaired after manual monitoring; and H_4 —system is without failures and under manual monitoring.

On the base of the state transition diagram for a Markov's process shown in Fig. 4, we can write the system of Chapman–Kolmogorov's equations according to the general rule for a stationary process [3]—a set of equations has for each state H_i on the left-hand side the equilibrium, a probability of a given state P_i multiplied by the total rate of all departures

Figure 4. Markov's state transition diagram for system with continuous operation, built-in-test equipment and manual monitoring.

translating from this state, and on the right-hand side, the sum of rates of all arrivals translating into the i th state multiplied by the probabilities of the states; consequently,

$$\begin{aligned}\mu_1 P_1 &= a\lambda P_0 \\ \lambda_m P_2 &= (1-a)\lambda P_0 \\ \mu_m P_3 &= \lambda_m P_2 \\ \mu_m P_4 &= \lambda_m P_0.\end{aligned}$$

The normalizing condition is $P_0 + P_1 + P_2 + P_3 + P_4 = 1$.

After transformation of the above-mentioned set of equations we can obtain the value for $P_i (i = 1 \dots 4)$ via P_0 :

$$\begin{aligned}P_1 &= \frac{a\lambda}{\mu} P_0 \\ P_2 &= \frac{(1-a)\lambda}{\lambda_m} P_0 \\ P_3 &= \frac{\lambda_m}{\mu_m} P_2 = \frac{(1-a)\lambda}{\lambda_m} P_0 \\ P_4 &= \frac{\lambda_m}{\mu_m}.\end{aligned}$$

Value of P_0 can be obtained by replacement $P_i (i = 1 \dots 4)$ in the normalizing equation $\sum_{i=0}^4 P_i = 1$:

$$\begin{aligned}P_0 + \frac{a\lambda}{\mu} P_0 + \frac{(1-a)\lambda}{\lambda_m} P_0 \\ + \frac{(1-a)\lambda}{\mu_m} P_0 + \frac{\lambda_m}{\mu_m} P_0 &= 1 \\ P_0^{-1} &= 1 + \frac{a\lambda}{\mu} + \frac{(1-a)\lambda}{\lambda_m} \\ &+ \frac{(1-a)\lambda}{\mu_m} + \frac{\lambda_m}{\mu_m}.\end{aligned}$$

Let us define the unavailability U of the examined system.

Unavailability can be defined as the probability that an item will not operate correctly at a given time and under specified conditions [4]. Mathematically, unavailability is 1 minus the availability A .

For the examined system $A = P_0, U = 1 - A = P_1 + P_2 + P_3 + P_4$.

For a highly reliable system with $\lambda \ll \mu, \lambda_m \ll \mu_m$ approximately $P_0 \rightarrow 1$.

Figure 5. The graphic of function $T_m = f(a)$.

In this case the system unavailability U is defined as follows:

$$U = \sum_{i=1}^4 P_i \cong \frac{a\lambda}{\mu} + \frac{(1-a)\lambda}{\lambda_m} + \frac{(1-a)\lambda}{\mu_m} + \frac{\lambda_m}{\mu_m}. \quad (1)$$

By differentiating Equation (1) with respect to λ_m , we get

$$\frac{dU}{d\lambda_m} = -\frac{(1-a)\lambda}{\lambda_m^2} + \frac{1}{\mu_m}. \quad (2)$$

Setting Equation (2) equal to zero we get optimal value of λ_m

$$\frac{1}{\lambda_m^2} = \frac{1}{\mu_m(1-a)\lambda}. \quad (3)$$

From Equation (3) we can obtain an expression for optimal monitoring time $T_m = 1/\lambda_m$:

$$T_m^2 = \frac{\tau_m T_0}{1-a} \text{ or } T_m = \sqrt{\frac{\tau_m T_0}{1-a}}. \quad (4)$$

The graphic of function $T_m = f(a)$ is shown in Fig. 5.

For the special case of a full monitoring system $a \rightarrow 1$, the monitoring time $T_m \rightarrow \infty$. This means that if the system has a built-in test equipment for 100% monitoring, the manual monitoring of such a system is not needed.

The system has $T_0 = 2500$ h, $\tau_m = 2$ h. Half of the system is under monitoring by the built-in test equipment ($\alpha = 0.5$). In accordance with Equation 4 $T_m = \sqrt{2 \times 2 \times 2500} = 100$ h.

For optimal results (the highest availability), approximately one inspection should be performed every 4 days.

Optimal Monitoring of the System with Periodical Sessions of Operation

Periodical sessions of operation are typical for professional communication channels (CCs); for example, during conversations between the pilot and the controller in an Air Traffic Control (ATC) system [5].

The following symbols have been used to develop equations for the model:

- λ = failure rate
- μ = repair rate
- A = availability
- h_i = probability of being in state H_i
- T_m = periodicity of test operations with parameter of Poisson's flow
- $\omega = 1/T_m$
- t_m = time of test operations
- τ = parameter of exponential distribution of t_m
- t_{f1} = time of failure fixation by human operator
- $v_1 = 1/t_{f1}$ = parameter of exponential distribution of t_{f1}
- t_{f2} = time of failure fixation by automatic test system
- $v_2 = 1/t_{f2}$ = parameter of exponential distribution of t_{f2}
- T_c = periodicity of communication demands with parameter of Poisson's flow $\varphi = 1/T_c$
- t_c = time of communication session
- $\psi = 1/t_c$ = parameter of exponential distribution of t_c
- t_n = mean time of test interruption in the case of communication session begins
- $v_3 = 1/t_n$ = parameter of exponential distribution of t_n
- t_R = time of repeat demand on communication in the channel with failure

η = parameter of exponential distribution of t_R

Strategy 1: Communication Channel Does Not Have the Built-In Test Equipment. In the case when the test equipment is absent, the CC failure is detected by the operator during the process of operation.

In this case, it is possible to clarify the process of the CC failure detection by the time diagram (Fig. 6). The CC with an operational set of the equipment starts functioning at time t_0 . After some operation time T_0 , the failure of the main set of the communication equipment happens at the moment of time t_1 . However, due to the absence of an automatic test system, the fixation of the failure does not happen. After some time T_c , at the moment t_2 , the operator receives the requirement by a communication, for example, in the form of a request from the transport object. The operator does not know about the malfunction of the operation of the CC. The operator transmits the answer for the request to the transport object. In this case, the object does not receive the answer and after some time T_R repeats the request. The delivery of the repeated request in moment t_3 is the information about the malfunction of CC to the operator. In such a case, the operator goes over to the CC with the reserve on-ground communication equipment, fixing the failure of the main set of the equipment. A similar process iterates in the case of the refusal of the reserve radio station too.

The behavior of the examined system is described by the state transition diagram (Fig. 7), where H_1 —completely good state of the CC equipment; H_2 —communication session in CC; H_3 —failure of the main CC system; H_4 —communication session in the CC with failure of the main communication radio aid; H_5 —repeat demand on communication in CC with failure of equipment;

Figure 6. Time diagram of failure detection for test strategy 1.

and H_6 —detection of the failure state of the main communication radio aid, switch over to the reserve one.

Solving forward Kolmogorov's differential equation system by describing the operation of the examined channel it is possible to define A_1 availability of the channel with the first test strategy:

$$A_1 = (1 + a_1)/(1 + a_1 + a_2), \quad (5)$$

where

$$a_1 = \lambda[\gamma_1(1 + \beta) + 1/\varphi], \quad a_2 = \beta,$$

$$\gamma_1 = 1/\mu + 1/\eta + 1/\nu_1, \quad \beta = \varphi/(\lambda + \psi).$$

Comparing Equation (5) with the equation for the A_0 availability of the ideal system (immediate failure detection, immediate switchover, nonfailure switch) [6], it is possible to come to a conclusion that $A_1 = A_0$ with nonlimited increase of the intensity of communication φ and the reduction of the failure detection time ($\nu_1 \rightarrow \infty$).

It is possible to evaluate the deterioration of the reliability in the real CC in comparison with the ideal one with the help of the reliability deterioration coefficient

$$V_1 = (1 - A_1)/(1 - A_0).$$

The function of influence of average time between communication session T_c and average switch time t_{f1} for the CC are given (see in Fig. 8 line 1 for $t_{f1} = 2$ min and line 2 for $t_{f1} = 10$ s).

Strategy 2: Communication Channel Has the Built-In Test Equipment with Diagnosis Procedures during Communication Sessions.

At present many of the communication systems have the built-in test equipment with diagnosis procedures during communication

Figure 7. State transition diagram for test strategy 1.

Figure 8. Deterioration of the reliability in the real communication channel with test strategy 1.

Figure 9. State transition diagram for test strategy 2.

sessions. The behavior of the examined system with the mentioned test strategy can be described by the graph of states submitted in Fig. 9, where the symbols of states entered earlier are saved.

The availability A_2 of the channel with the second test strategy may be defined by solution of the Kolmogorov's equation system, which describes the graph mentioned previously (Fig. 9):

$$A_2 = (1 + a_1)/(1 + a_1 + a_2),$$

where

$$a_1 = \lambda[\gamma_2(1 + \beta) + 1/\varphi], \quad a_2 = \beta, \\ \beta = \varphi/(\lambda + \psi), \quad \gamma_2 = 1/\mu + 1/\nu_2.$$

The analysis of the reliability deterioration coefficient $V_2 = (1 - A_2)/(1 - A_0)$ shows the dependency similar to the one submitted in Fig. 8.

Figure 10. State transition diagram for test strategy 3.

Strategy 3: Communication Channel Has a Periodical Test in the Pauses between Communication Sessions. In this case the process of CC operation can be described by the following states: H_1 —good condition of CC equipment, absence of the communication session and test operations; H_2 —test in the channel without communication session; H_3 —communication session; H_4 —demand on communication in the test period; H_5 —failure of CC equipment when the communication is paused; H_6 —test of system with failure; H_7 —demand on communication in the channel with failure of equipment; H_8 —failure fact fixation by automatic test system or by human operator. There is a state transition diagram of the examined system showed in Fig. 10. The availability A_3 of the examined CC is defined by equation

$$A_3 = \sum_{i=1}^3 h_i.$$

By forming and solving the Kolmogorov's equation system describing the graph of the states, it is possible to define probabilities $h_i, i = 1, \dots, 8$, and the availability A_3 :

$$A_3 = (1 + a_1)/(1 + a_1 + a_2),$$

where

$$\begin{aligned}
 a_1 &= \omega/(\lambda + \varphi + \tau)[\lambda(1/\mu + 1/v_2) + \varphi/v_3 \\
 &\quad + \lambda\varphi/(\lambda + \psi)(1/\mu + 1/v_1)] \\
 &\quad + \lambda/(\omega + \varphi)[1 + \omega(1/\mu + 1/v_2) \\
 &\quad + \varphi(1/\mu + 1/v_1) + \varphi/(\lambda + \psi)(1/\lambda + v_1)] \\
 a_2 &= (\lambda + \varphi)^{-1}[\omega(\lambda + \varphi + \psi)/(\lambda + \varphi + \tau) + \varphi].
 \end{aligned}$$

The reliability deterioration of the real CC may be evaluated by the coefficient

$$V_3 = (1 - A_3)/(1 - A_0).$$

The analysis of the $V_3(\omega)$ shows that it is a unimodal function with the extremes in ω_{opt} point.

The expression for the definition of $T_{m,\text{opt}} = 1/\omega_{\text{opt}}$ is possible to find out from the condition $dA_3/d\omega = 0$. In a general case, the expression for the definition $T_{m,\text{opt}}$ appears quite cumbersome, but for the practical crucial case of the highly reliable systems ($\lambda \ll \mu$) with a short time for the failure fixation ($\mu \ll v_1, \mu \ll v_2$), the following approximate expression is justified for the definition of the optimal test periodicity:

$$\begin{aligned}
 T_{m,\text{opt}}^{-1} &= v_3\varphi^{-1}\{\lambda + [(\lambda - \varphi^2/v_3)^2 \\
 &\quad + \lambda\varphi\tau/v_3]^{1/2}\} - \varphi.
 \end{aligned}$$

Let us examine the CC availability of an ATC system in an airport area. The controller's channel radio stations are operating in the day/night operation regime. The sessions of communication are carried out at random moments of time. The failures of the radio stations could be fixed by the objective technical test aids executing the periodical test, or subjectively according to the operator's evaluation. There are $V(T_m)$ dependencies for various MTBF T_0 and typical average meanings of the characteristics of the ATC CC showed in Fig. 11. There are functions $T_{m,\text{opt}}(T_0)$ for the various T_c periodicity of communication session and time of test interruption t_n showed in Figs 12 and 13.

Figure 11. Functions $V(T_m)$ for test strategy 3.

Figure 12. Functions $T_{m,\text{opt}}(T_0, T_c)$.

Optimal Inspection Frequency in order to Maximize Profit

The model is developed on the premise that the equipment under repair leads to zero output, thus less profit. Furthermore, if the equipment is inspected too often, there is a danger that there may be an increase in costs due to factors such as loss of production, cost of materials, and wages than losses due to breakdowns. The following assumptions are associated with this model [7]:

Figure 13. Functions $T_{m, \text{opt}}(T_0, t_n)$.

- The equipment failure rate is a function of inspections.
- Times of inspection are exponentially distributed.
- Equipment failure and repair rates are constant.

The following symbols are used to develop equations for the model:

- n = number of inspections performed per unit of time
- $1/\theta$ = mean of exponentially distributed inspection times
- p = profit at no downtime losses
- C_i = average inspection cost per uninterrupted unit of time
- C_r = average cost of repair per uninterrupted unit of time
- $\lambda(n)$ = equipment failure rate for maintenance strategy with n number of inspections
- μ = equipment repair rate

Profit per unit of time is expressed by Dhillon [7] as

$$\begin{aligned} \text{PR} &= p - \text{PL}_i - \text{PL}_r - \text{IC} - \text{RC} \\ &= p - \frac{pn}{\theta} - \frac{p\lambda(n)}{\mu} - \frac{nC_i}{\theta} - \frac{C_r\lambda(n)}{\mu}, \quad (6) \end{aligned}$$

where

PL_i = production output value loss per unit of time due to inspections

PL_r = production output value loss per unit of time due to repairs

IC = inspection cost per unit of time

RC = repair cost per unit of time.

By differentiating Equation (6) with respect to n and then equating it to zero yield

$$\frac{d\text{PR}}{dn} = -\frac{p}{\theta} - \frac{p}{\mu} \frac{d\lambda(n)}{dn} - \frac{C_i}{\theta} - \frac{C_r}{\mu} \frac{d\lambda(n)}{dn} = 0. \quad (7)$$

Rearranging Equation (7), we get

$$\begin{aligned} \frac{d\lambda(n)}{dn} &= -\left[\frac{1}{\theta}(p + C_i)\right] / \left(\frac{p}{\mu} + \frac{C_r}{\mu}\right) \\ &= -\frac{\mu(p + C_i)}{\theta(p + C_r)}. \end{aligned} \quad (8)$$

The value of n will be optimal when the left and right sides of Equation (8) are equal. At this point, the profit will be at its maximum value.

Assume the failure rate of a manufacturing system is defined as $\lambda(n) = \lambda_0 e^{-n}$, where λ_0 is the system failure rate at $n = 0$.

Let us develop an expression for the optimal value of n with the aid of Equation (8); using $\lambda(n) = \lambda_0 e^{-n}$ in Equation (8) yields

$$-\lambda_0 e^{-n} = -\frac{\mu(p + C_i)}{\theta(p + C_r)} \quad (9)$$

and by rearranging Equation (9), we get

$$n^* = \ln \left[\frac{\lambda_0 \theta (p + C_r)}{\mu (p + C_i)} \right], \quad (10)$$

where

n^* = optimal manufacturing system inspection frequency.

Suppose that we have the following data:

p = \$10,000 per month

$\lambda_0 = 2$ failures per month
 $\mu = 25$ repairs per month
 $\theta = 100$ per month
 $C_i = \$75$ per month
 $C_r = \$400$ per month.

Determine the optimal value of n by using Equation (10).

By inserting the specified data values into Equation (10), we obtain

$$n^* = \ln \left[\frac{2 \times 100 \times (10,000 + 400)}{25 \times (10,000 + 75)} \right] = 2.11.$$

For optimal performance, approximately two inspections per month should be performed [7].

CONCLUSIONS

Monitoring strategies are a key element of reliability-centered maintenance (RCM), which is the most proven proactive approach for developing maintenance programs from scratch. RCM includes preventive, predictive, and detective (failure finding) activities. Preventive maintenance includes activities that are scheduled and executed to replace components or restore them to their original condition from their apparent condition at the time. Predictive maintenance also known as *condition-based maintenance* or *on-condition maintenance* includes activities performed to look for signs of impending failures so that corrective maintenance can be done before equipment functionality is lost. RCM programs provide balance of cost versus reliability that is tailored specifically to each system in its operating environment. Maintenance optimization arises from the need to improve maintenance programs that are failing to meet the desired performance expectations. *Decision optimization* refers to the use of any one of several optimization tools. These tools are used to make decisions about component replacement, repair versus replace, inspection intervals, and repairs. Optimization tools enhance reliability and reduce costs. They add value to the output of RCM and may lead to modifications in

RCM output decisions. There are many mathematical approaches to solving typical maintenance problems and monitoring tasks. Many of them have come from the field of operations research. Some of the problems that can be solved include [8] optimizing of the following:

- the age at which equipment replacements are made using various applications and operating cost profiles to determine the most cost-effective age for replacement;
- the decision for the time swap duty and standby equipment combinations to achieve maximum backup availability and reduce the risk of multiple failures;
- the decision as to when to replace capital equipment to maximize discounted cash flow benefits or to minimize total cost;
- intervals between preventive replacements to achieve target availability;
- the time for group replacements of large numbers of identical assets instead of replacement as they fail in order to minimize overall cost;
- inspection frequencies to maximize profits, minimize downtime, and maximize availability of emergency equipment;
- decision making related to overhaul and repair versus replacement policies and cost limits.

Many maintenance problems can be solved using data analysis tools with special software [9–11]. There are many of these software tools available, most are stand-alone programs that can be interfaced or integrated with corporate databases. Several collect condition-monitoring signals that are input from field sensors and use that data in real time with history data and economic inputs to produce recommendations either to run or not run equipment or to shut it down for work. Another powerful modern technique is simulation modeling of the complex systems [12,13]. These models can show the effect of various monitoring strategies and reliability increase at

different points in the systems and help focus engineering improvement efforts more effectively.

Continuous improvement of maintenance management will be possible due to the utilization of emerging techniques and technologies in areas that are considered to be of higher impact as a result of the previous steps of the management process [14].

Regarding the application of new technologies to maintenance, the “e-maintenance” concept is put forward as a maintenance support, which includes the resources, services, and management necessary to enable proactive decision process execution. This support not only includes e-technologies but also e-maintenance activities (operations or processes) such as e-monitoring, e-diagnosis, and e-prognosis [15].

References 16–21 present a set of techniques that can be used to improve involvement of maintenance personnel in maintenance improvement programs, and a review of new technologies arising in maintenance, respectively.

OPTIMAL RELIABILITY ALLOCATION

YASHWANT K. MALAIYA
Computer Science Department,
Colorado State University,
Fort Collins, Colorado

INTRODUCTION

A large system is implemented by using a set of interconnected subsystems. While the architecture of the overall system is often fixed because of the functional requirements, implementation choices are generally available for individual subsystems. A designer needs to achieve the target reliability while minimizing the total cost, or alternatively maximize the reliability while using only the available budget. Intuitively, some of the lowest reliability components may need special attention to raise the overall reliability level. Such optimization problems arise while designing a complex software or a hardware system. Such problems also arise in mechanical or electrical systems. A number of studies since 1960 have examined some of the computational aspects of such problems [1].

All the subsystems are essential in a nonredundant system. However, an individual subsystem can often be made more reliable by using a more costly implementation. This additional cost may represent wider columns in a building or more thorough testing of software. In redundant implementations, higher reliability can sometimes be achieved by using several copies of a subsystem, such that the system incorporates a *parallel* or a *k-out-of-n* configuration.

The problem formulation is considered in the next section, followed by approaches used for setting up an optimization problem. As a detailed example, software reliability allocation is examined in detail with a numerical illustration. The last section considers reliability allocation in general complex systems.

ALLOCATION AS AN OPTIMIZATION PROBLEM

We consider a system that has been designed at a higher level as an assembly of appropriately connected subsystems. The functionality of each subsystem is often unique; however, there can be several choices for many of the subsystems that provide the same functionality but differently reliability levels.

Here we consider the problem formulation for a common and widely applicable case. Let there be n subsystems $SS_i, i = 1, \dots, n$, each with reliability R_i and cost C_i . Let the cost C_i be a function of the reliability given by $f_i(R_i)$, this is generally referred to as the *cost function*. Let C_s and R_s represent the total system cost and the overall reliability and let R_{ST} be the specified target reliability. If all the subsystems are essential to the system and if their failures are statistically independent, the system can be modeled as a *series system*. The cost minimization problem can be stated as

$$\begin{aligned} \text{Minimize} \quad & C_s = \sum_{i=1}^n C_i = \sum_{i=1}^n f_i(R_i) \end{aligned} \quad (1)$$

$$\begin{aligned} \text{Subject to} \quad & R_{ST} \leq R_s \\ \text{i.e., } & R_{ST} \leq \prod_{i=1}^n R_i \quad \text{since} \\ & R_s = \prod_{i=1}^n R_i. \end{aligned} \quad (2)$$

Note that Equation (1) assumes that the cost of interconnecting the subsystems is negligible. An alternative problem would be to maximize R_s while keeping C_s less than or equal to the allocated cost budget.

Depending on the type of the system, the i th subsystem SS_i may have several implementation choices with different reliability values:

1. The subsystem can be made more reliable by extending a continuous attribute (e.g., diameter of a column in building or time spent for software testing).
2. Different vendors may offer their own implementations of SS_i at different costs.
3. It may be possible to use multiple copies of SS_i (e.g., double wheels of a truck) to achieve higher reliability. Often the number of copies is constrained between a minimum (often one) and a maximum number because of implementation issues.

In the first case, both cost and the reliability can be varied continuously, whereas in the other two cases, the choices are discrete. In the first case, we can define a continuous cost function. In the second case too, the market forces may impose a cost function. In the third case, the subsystem may be modeled as a *parallel* or *k-out-of-n* system for reliability evaluation, provided the failures are statistically independent. A number of publications on reliability allocation consider only the third case, where the optimization problem becomes an integer optimization problem. It becomes a 0–1 optimization problem when choices are discrete and a component from a given list of candidates is either used or not used [2].

THE COST FUNCTION AND PROBLEM SETUP

It is reasonable to assume that the cost function f_i would satisfy these three conditions [3]:

1. f_i is a positive function;
2. f_i is nondecreasing, thus higher reliability will come at a higher cost;
3. f_i increases at a higher rate for higher values of R_i .

The third condition leads to the fact that it can be very expensive to achieve the reliability value of 1. In fact, for software, it has been shown that it is infeasible to achieve ultra-high reliability in software [4]. Note

that the cost function, in general, will also be a function of the relative complexity of the subsystem.

In some cases, the cost function can be derived from basic considerations, as we will do below for software reliability. In other cases, it may be derived empirically by compiling data for different choices. The cost function is often stated in terms of the reliability; for example, the cost function proposed by Mettas [3] is given in terms of the maximum and minimum achievable reliability values.

In some cases, there are choices that can be made that can enhance reliability with little or no additional cost, sometimes by using newer technology. For example, some disciplined software development processes have been found to yield more reliable software with the same effort. We assume that such choices have already been made, and optimization is sought by exploiting the available choices of attributes.

The cost function can also be given in terms of the failure rate as illustrated below for software reliability allocation.

A transformation of Equation (2) can be obtained by logarithms of both sides of the equation [5–7]

$$\ln(R_{ST}) \leq \sum_{i=1}^n \ln(R_i). \quad (3)$$

The transformation in Equation (3) can reduce the problem to a linear optimization problem. In some cases, the term $\ln(R_i)$ also has a well-defined physical significance and is termed the *failure rate*. When the failure rate of a subsystem SS_i is constant, its reliability is given by an exponential relationship $R_i(t) = \exp(-\lambda_i t)$, the system failure rate is given by the summation of the subsystem failure rates and hence Equation (3) can be restated as

$$\lambda_{ST} \geq \sum_{i=1}^n \lambda_i. \quad (4)$$

The failure rate is itself a frequently used reliability metric. In some cases such as in software reliability engineering, it is the failure rate that is often specified [8,9]. The cost

function of a subsystem can also be given in terms of its failure rate. If the cost C_i is given by the function $f_i(\lambda_i)$, Equation (1) can be restated as

$$\text{Minimize} \quad C_S = \sum_{i=1}^n C_i = \sum_{i=1}^n f_i(\lambda_i). \quad (5)$$

For example, let us consider software reliability. When a software is tested, defects in it are found and removed by debugging. A program tested more thoroughly will have fewer bugs and hence higher reliability. Several models relating software reliability growth with the time spent in testing, have been proposed and validated. These are termed software *reliability growth models* (SRGMs). For the popular *exponential software reliability growth model* [8–10], the failure rate as a function of testing time d is given by

$$\lambda_i(d) = \lambda_{0i} \exp(-\beta_i d),$$

where λ_{0i} and β_i are the model parameters. It should be noted that λ_{0i} depends on initial defect density and β_i depends inversely on program size [11]. If we assume that the variable cost is dominated by the testing time, the cost is given by the following function, which satisfies the three conditions mentioned above

$$d(\lambda_i) = \frac{1}{\beta_i} \ln \left(\frac{\lambda_{0i}}{\lambda_i} \right). \quad (6)$$

RELIABILITY ALLOCATION FOR BASIC SERIES AND PARALLEL SYSTEMS

The reliability allocation problem for two basic reliability structures such as *series* and *parallel* can be solved by linearizing the constraints [1,2,7]. In a *series* system, the constraint is given in Equation (2) above, which can be linearized by rewriting it as given in Equation (3) above, which may then be solved relatively easily. An example is given below for software reliability allocation.

In a *parallel system*, functionally identical subsystems are configured such that correct operation of at least one of them assures a correctly functioning system. It is assumed

that any overhead in implementing such a system is negligible. In real systems, the overhead involved will result in a lower level of reliability. In a number of studies, the problem assumes that the reliability of a subsystem can be increased by using functionally identical components in parallel [2,7]. For parallel systems, the constraint is given by

$$R_{ST} \leq 1 - \prod_{i=1}^n (1 - R_i). \quad (7)$$

The constraint can be linearized by using logarithms of the complements of reliability. Thus, Equation (7) can be rewritten as

$$\ln(1 - R_{ST}) \geq \sum_{i=1}^n \ln(1 - R_i). \quad (8)$$

Elegbede *et al.* have recently shown [7] that if the cost function satisfies the three properties given above, the cost is optimal if the all the parallel components have the same cost. For software, computer hardware, and mechanical systems, the number of discrete parallel component is likely to be very small.

RELIABILITY ALLOCATION IN SOFTWARE SYSTEMS

Let us examine the problem of software reliability allocation [6], which serves as a good illustration. Typically, a software consists of sequentially executed components, where only one of them is under execution at a time. Each component can be independently tested and debugged to reduce the failure rate below a target value. In some cases, the reliability of a component can be further increased by replication. For replication to be effective, each replicated version must be developed independently such that the failures are relatively independent. The impact of replication can be evaluated by assuming statistical independence. However, it has been shown that sometimes the statistical correlation can be significant, requiring analysis that is more complex.

In this example, we consider a nonredundant implementation of software, divided into n sequential components [6], which is a common case. Let us assume that a component i is under execution for a fraction x_i of the time where $\sum x_i = 1$ [5]. Software reliability is often described in terms of the failure rates. Then the reliability allocation problem can be written as

$$\text{Minimize} \quad C = \sum_{i=1}^n \frac{1}{\beta_i} \ln \left(\frac{\lambda_{0i}}{\lambda_i} \right) \quad (9)$$

$$\text{Subject to} \quad \lambda_{ST} \leq \sum_{i=1}^n x_i \lambda_i. \quad (10)$$

Solution: let us solve the problem posed by Equations (9) and (10) by using the Lagrange multiplier approach by finding the minimum of

$$F(\lambda_1, \dots, \lambda_n) = C + \theta(\lambda_1 + \dots + \lambda_n) - \lambda_{ST},$$

where θ is the Lagrange multiplier. The necessary conditions for the minimum to exist are (i) the partial derivatives of the function F are equal to 0, (ii) $\theta > 0$, and (iii) $x_1 \lambda_1 + x_2 \lambda_2 + \dots + x_n \lambda_n = \lambda_{ST}$ [6]. Equating the partial derivatives to 0 and using the third condition, the solutions for the optimal failure rates are found as following:

$$\begin{aligned} \lambda_1 &= \frac{\frac{\lambda_{ST}}{x_1}}{\sum_{i=1}^n \frac{\beta_1}{\beta_i}} \quad \lambda_2 = \frac{\beta_1 x_1}{\beta_2 x_2} \lambda_1 \quad \dots \\ \lambda_n &= \frac{\beta_1 x_1}{\beta_n x_n} \lambda_1. \end{aligned} \quad (11)$$

The optimal testing times of the individual modules, $d_i, i = 1$ to n , are given by Equation (12) below

$$\begin{aligned} d_1 &= \frac{1}{\beta_1} \ln \left(\frac{\lambda_{10} x_1 \sum_{i=1}^n \frac{\beta_1}{\beta_i}}{\lambda_{ST}} \right) \quad \text{and} \\ d_i &= \frac{1}{\beta_i} \ln \left(\frac{\lambda_{i0} \beta_i x_i}{\lambda_1 \beta_1 x_1} \right). \end{aligned} \quad (12)$$

Note that d_i is positive if $\lambda_i \leq \lambda_{i0}$. The testing time for a module must be nonnegative. If any of the testing times obtained using Equation (12) are negative, the optimization problem may have been solved iteratively [6] or using special approaches. Sometimes a reused subsystem has a significantly higher reliability because of past testing, which may result in $\lambda_i \geq \lambda_{i0}$. Since the reused subsystem is already reliable enough, it would make sense to spend any testing effort on the other subsystems.

In software reliability engineering, the assumptions involved in formulation of the exponential model imply that the parameter β_i is inversely proportional to the software size [8,11], measured in terms of the lines of code. In the examples below, we assume that value of x_i is proportional to the subsystem code size. The values of λ_i and λ_{i0} do not depend on size but on the initial defect densities [11] at the beginning of testing. Thus, if the exponential model indeed holds, the Equation (11) states that the optimal values of the post-test failure rates $\lambda_1, \dots, \lambda_n$ are equal. In addition, if the initial defect densities are also all equal for all the components, then the optimal test times for each module is proportional to its size.

The parameter values needed for Equations (12) and (13) may be determined by some initial testing or using empirical relationships.

Example 1. A software system uses five functional components B1–B5. This example has been constructed assuming sizes 1, 2, 3, 10, and 20 KLOC (thousand lines of code) respectively, and the initial defect densities of 10, 10, 10, 15, and 20 defects per KLOC, respectively. Let us assume that measured parameter values are given in the top three rows, which are the inputs to the optimization problem. The solution obtained using Equations (11) and (12) are given in the two bottom rows. The test cost has been minimized so that the overall failure rate is less than or equal to 0.04 per unit time. Here the time units can be person hours of testing time, or hours of CPU time used for testing.

Component	B ₁	B ₂	B ₃	B ₄	B ₅
β_i	4.59×10^{-3}	2.30×10^{-3}	1.53×10^{-3}	4.59×10^{-4}	2.30×10^{-4}
λ_{i0}	0.046	0.046	0.046	0.069	0.092
x_i	0.028	0.056	0.083	0.278	0.556
Optimal λ_i	0.04	0.04	0.04	0.04	0.04
Optimal d_i	30.1	60.1	90.2	1184	3620

Note that the optimal values of λ_i for the five components are equal, even though they started with different initial values. This implies that a substantial part of the test effort is allocated to largest components. The total cost in terms of testing is 4984 unit time.

If the total test time were equally distributed for all five components, it would have resulted in significantly higher failure rate of 0.055 per unit time.

RELIABILITY APPORTIONMENT RULES

The discussion in the section above suggests that some preliminary rules may be used for obtaining initial reliability apportionments before a more thorough optimization. Some apportionment rules have been suggested in the literature [5].

Equal Reliability Apportionment. One can test a set of software components, such that at the end they all individually have the failure rate equal to the target failure rate for the system. Newly developed modules need to be tested until their reliability equals that of the existing modules.

Complexity Based Apportionment. The software size itself is a complexity metric. Thus, the available test time can be apportioned in proportion to the software size.

Impact Based Apportionment. A component that is executed more frequently, or is more critical in terms of failures, should be assigned more resources. Note that in the analysis above, x_i can be chosen to reflect the product of frequency and criticality.

RELIABILITY ALLOCATION FOR COMPLEX SYSTEMS

Some systems can have complex reliability allocation choices and may require an iterative approach [1,2,7,12]. Such an approach is also needed if the objective function is multi-objective and includes both total cost and the system reliability [1]. An iterative approach involves the following steps [12]:

1. Design the system using functional subsystems.
2. Perform an initial apportionment of cost or reliability attributes based on suitable apportionment rules or preliminary computation.
3. Predict system reliability.
4. Determine if reallocation is feasible and will enhance the objective function. If so, perform reallocation.
5. Repeat until optimality is achieved.
6. See if this meets the objectives. If not, consider returning to step 1 and revising the design at a higher level.
7. Finalize the design with recommended reliability allocation and the cost projections.

Several optimization methods can be used for steps 2–5 above. These can be classified into three approaches [1] as follows:

1. *Exact Methods.* When the problem is not large, exact methods can be desirable. In general, the problem can be a non-linear optimization problem. In a few cases, the problem can be transformed into a linear problem, as shown in the example above.
2. *Heuristics Based Methods.* Several heuristics for reliability allocation have been developed. Many of them

are based on identifying the variable to which the solution is most sensitive, and varying its value.

3. *Metaheuristic Algorithms*. These algorithms are based on artificial reasoning. The best known of them are *genetic algorithms*, *simulated annealing*, and *tabu-search*. These algorithms can be useful when the search space is large and approximate results are sought.

Reliability allocation in systems with replicated subsystems can encounter correlated failures and thus would need a more careful modeling. In software, such correlation can be significant [13]. The factors that affect technology dependant reliability attributes such as defect density in software [14] have been studied by researchers and are still being researched.

Several software tools, both general purpose [15] and special purpose [6], have been developed that can simplify setting up and solving the optimal allocation problem. Reliability allocation problem can also be formulated to address other reliability attributes such as availability or maintainability.

OPTIMAL REPLACEMENT AND INSPECTION POLICIES

MAARTEN-JAN KALLEN
HKV Consultants, Lelystad,
The Netherlands

This article covers the selection of policies for the timing of inspections or replacements, which are optimal according to some predefined criterion. The primary application of such policies is in problems of maintenance optimization. Mechanical devices, electrical components, and civil infrastructures are examples of items which generally need some form of maintenance. Inspections and replacements in various forms are actions that may be performed as part of a maintenance strategy. Repairs may be performed before an item has failed, in which case it is a preventive maintenance action, or it may be performed after an item has failed in which case it is a corrective maintenance action. Depending on the risk involved with the failure of an item, the decision maker will have a preference for one of these two types of maintenance actions.

The times at which failures occur are usually uncertain. For systems that depend on the availability of an item, for example, a conveyor belt in a production line, the failure of such an item results in unplanned and costly disruptions of production. It will therefore pay to perform inspections and repair items preventively. An optimal policy describes how often these inspections and repairs should be performed, such that the cost of these maintenance actions is well balanced against the cost of simply letting an item fail. The decision to preventively replace an item may be based on its condition, in which case the policy may also include the quality criteria by which an item will be deemed necessary to be replaced or not.

Optimal maintenance policies are obtained using mathematical models, which

are almost always probabilistic in nature. Deterministic models are only applicable when the occurrence of failures is deterministic or when (probabilities of) the outcomes of an inspection are assumed to be known beforehand to the decision maker. Many models have been proposed for the purpose of optimizing maintenance actions of which Refs 1–10 all give an overview in some form or another. In the following section, many of the common assumptions that characterize these models are mentioned. The next section lists three cost-based criteria that can be used to compare different maintenance policies. This is followed by a section with the mathematical details of the two most common models: age-based and condition-based replacements.

MODEL ASSUMPTIONS AND NOTATIONS

Maintenance models are built upon a number of assumptions that help to keep the calculations tractable. They also ensure that the resulting policies are easy to implement in practice.

Inspections are generally performed to determine the condition of an item. However, in some cases they may be required to ascertain if an item is still functional or not. This means that a failure of the item is not noticed until an inspection is performed. Inspections are almost always assumed to be instantaneous. This is generally a good approximation if the duration of an inspection is negligible compared to the lifetime of the item. The same assumption is often made for repairs, although there are many applications in which the duration of a repair is relevant. This is especially true for cases in which the availability of an item is an important operating characteristic of the maintenance policy. Inspections are either periodic or not, where in the latter case the times between inspections may differ. An example of an aperiodic inspection policy is one in which the frequency of inspections increases

together with the age of an item.

The single most important assumption in maintenance policies is that a repair brings an item to an as-good-as-new state such that a repair is equivalent to a replacement. Implicit in this assumption is that the operating environment of an item after it has been replaced is the same as it was before the replacement. This means that the deterioration of the item is the same after each replacement or, in mathematical terms, the probability distribution of the time to failure is the same after each replacement. This assumption allows for the use of the results in renewal theory (see **Limit Theorems for Renewal Processes**). Although models for partial repair (also referred to as *imperfect maintenance*) are relevant in real-life situations, they are outside the scope of this article.

The following section uses the concept of a cycle. Each time an item is replaced, a new cycle starts. The cycle ends when an item is replaced, which may be before or after it fails. During a cycle several types of costs may be incurred: cost of a preventive or corrective replacement, cost of one or more inspections, and possibly the cost of unavailability. The latter cost should be included if the occurrence of a failure may only be determined using an inspection. In the absence of such a penalty, the optimal policy would be not to inspect at all.

COST-BASED CRITERIA FOR POLICY EVALUATION

This section presents three cost-based criteria, whose purpose is to reduce future streams of costs (and rewards) to a single value for policy evaluation. Let $K(t)$ denote the costs incurred during a time span $[0, t]$ with $t > 0$. A renewal process $\{N(t), t \geq 0\}$ is a nonnegative integer-valued stochastic process, which registers the successive renewals in the time interval $[0, t]$. Let $F(t)$ be the cumulative probability distribution function of renewal time T and let $c(t)$ be the cost associated with a renewal at time t .

An optimal maintenance policy over a finite time-span (or bounded horizon) may

be determined by calculating the expected value, denoted by $EK(t)$, for each policy and to select the policy with the lowest value. If the choice of a maintenance policy, or a particular design of the system, affects the length of the service life of an object, it is beneficial to compare these policies or designs based on (possibly fictive) annuity payments to be made during the service life. Annuities are specified payments made at fixed time intervals. Specifying the costs of maintenance policies in terms of these (annual) payments enables one to compare policies, which entail different service lives.

The first and most common criterion for policy evaluation over an unbounded horizon is the criterion of expected average cost per unit time:

$$\lim_{t \rightarrow \infty} \frac{EK(t)}{t} = \frac{\int_{t=0}^{\infty} c(t) dF(t)}{\int_{t=0}^{\infty} t dF(t)}. \quad (1)$$

Therefore, if a cycle is completed every time a renewal occurs, then Equation (1) states that the (expected) long-run average cost is simply the expected cost incurred during a cycle divided by the expected length of a cycle. This criterion is a direct result of renewal reward theory [11, Theorem 3.16].

According to Ref. 12, Chapter 11, there are two other cost-based criteria, which may be used for evaluating maintenance policies: (i) the expected discounted costs over an unbounded horizon and (ii) the expected equivalent average costs per unit time. Using the criterion in Equation (1), one does not have a preference for the times at which costs are incurred. In other words, costs incurred in the near future are weighted no differently than costs incurred a long time from now.

Future costs (and rewards) can be discounted to their present value on the basis of a discount rate. The notion of discounting assumes that the future utility of money decreases in time. In practice, this means that costs incurred at future dates are less bothersome to us than costs incurred today. In mathematical terms, the (present) discounted value of the costs c_n in unit time $n = 0, 1, 2, \dots$ is defined to be $\alpha^n c_n$ with

$\alpha = [1 + (r/100)]^{-1}$, the discount factor per unit time and $r\%$ ($r > 0$) the discount rate per unit time. This formulation assumes that the timescale is divided in discrete units of time. For continuous types of discounting, we may assume any continuous, nonnegative, and nonincreasing function $\alpha(t)$ with the convention $\alpha(0) = 1$. The simplest example of such a function is the example of exponential discounting with $\alpha(t) = \exp\{-rt\}$ proposed by Samuelson [13]. The expected discounted costs over an unbounded horizon are given by

$$\lim_{t \rightarrow \infty} EK(t, \alpha(t)) = \frac{\int_{t=0}^{\infty} \alpha(t)c(t) dF(t)}{1 - \int_{t=0}^{\infty} \alpha(t) dF(t)}. \quad (2)$$

See Ref. 14, for a proof of this result with $\alpha(t)$ equal to the exponential discounting function mentioned above. For more on continuous forms of discounting, like exponential and hyperbolic discounting, see Ref. 15. The latter article is also concerned with the derivation of the second moment of the discounted costs. This information is interesting because it gives an indication of the amount of uncertainty involved with the optimal policy. Experience shows that an optimal policy in terms of expected (discounted) costs may also have large uncertainty associated with it [16]. This suggests that a decision maker may prefer to select a policy with slightly higher expected costs, but with an outcome that is less uncertain.

The expected equivalent average costs per unit time are given by

$$\lim_{t \rightarrow \infty} \frac{EK(t, \alpha(t))}{\int_{x=0}^t \alpha(x) dx}. \quad (3)$$

This criterion is obtained by constructing an infinite stream of costs (or rewards) with the same present discounted value as the expected discounted costs over an unbounded horizon. It relates the notions of the expected average costs and the expected discounted costs. This criterion is particularly well suited for the inclusion of initial investment costs into the decision model. The concept of life cycle costing is an example of an analysis in

which the costs of construction and demolition are also included when determining an optimal maintenance policy. Design decisions may influence the future costs of maintaining the item, such that the costs of different designs may be compared over the full life-time of an item.

COMMON MAINTENANCE POLICIES

By far the most common policies applied today are the age-based and condition-based replacement policies. The basic theory of both policies are described next (see also **Age Replacement Policies** and the section titled “Condition-Based Maintenance and Reliability” in this encyclopedia).

Age-Based Replacements

In an age-based maintenance policy, an item is replaced at age $\tau > 0$ or at a failure, whichever occurs first. It is assumed that failures are immediately noticed. Let c_1 denote the cost of a corrective replacement after a failure and c_2 the cost of a preventive replacement before a failure. We always assume that a preventive replacement is less costly compared to a corrective replacement, that is $c_1 > c_2$. The total costs incurred during the interval $[0, t]$ are

$$EK(t) = c_1 EN_1(t) + c_2 EN_2(t), \quad (4)$$

where $EN_1(t)$ and $EN_2(t)$ are the expected number of corrective and preventive replacements respectively. Using Equation (1) with

$$c(\tau) = \begin{cases} c_1, & T \leq \tau, \\ c_2, & T > \tau, \end{cases} \quad (5)$$

the expected average costs per unit time over an unbounded horizon are given by

$$\lim_{t \rightarrow \infty} \frac{EK(t)}{t} = \frac{c_1 F(\tau) + c_2 [1 - F(\tau)]}{\int_{t=0}^{\tau} [1 - F(t)] dt} = L(\tau). \quad (6)$$

Here $L(\tau)$ is the loss function for the replacement interval τ and $F(t) = \Pr\{T \leq t\}$ is the probability distribution function of the

Figure 1. Example of the loss function $L(\tau)$ for an age-based replacement policy giving the expected average costs as a function of the replacement interval τ .

renewal time T . An optimal policy τ^* is found by minimizing $L(\tau)$ with respect to τ . For a very large replacement interval Equation (6) states that only corrective replacements are performed: $L(\infty) = c_1/\mu$, with μ , the mean time to failure:

$$\mu = E[T] = \int_{x=0}^{\infty} x dF(x). \quad (7)$$

Let $r(x) = f(x)/(1 - F(x))$ denote the failure rate function of the distribution $F(x)$ (see **Hazard Rate Function**). If $r(x)$ is strictly increasing, then the minimum τ^* of the loss function $L(\tau)$ exists, but may be equal to infinity. Using heuristic arguments, Barlow and Proschan [17] show that it should always hold that $\tau^* \geq (c_2/c_1)\mu$. This is useful information, but in most cases the optimal replacement interval will be much larger than this lower bound. Note that the optimal replacement interval τ^* only depends on the ratio c_2/c_1 of the costs and not on the actual costs themselves, which can be seen by dividing the loss function in Equation (6) by c_1 . This changes the value at the minimum, but not its location and this also holds for an age-based replacement policy using discounted costs [18, p. 100].

Example. The following simple example helps to illustrate a typical result of an age-based replacement model. Let the lifetime of

an item be represented by a Weibull distribution with cumulative probability function

$$F(t) = 1 - \exp\left\{-\left[\frac{t}{b}\right]^a\right\},$$

with scale parameter $b = 5$ and shape parameter $a = 1.5$. The expected value of the lifetime T is then approximately 4.5 time units. Let $c_1 = \$300$ and $c_2 = \$50$, then the loss function $L(\tau)$ in Equation (6) may be plotted for a range of values of τ . This is shown in Fig. 1. Also shown in this figure are the individual contributions of preventive and corrective replacements to $L(\tau)$. It can be seen that the expected costs due to a preventive replacement decreases as the length of the replacement interval increases. This is due to the fact that the probability of a corrective replacement increases as replacements are performed less frequently. The minimum is attained at $\tau^* = 2.9$ time units with a value of $L(\tau^*) = \$56.81$. For large values of τ , the loss function approaches $c_1/\mu \approx \$300/4.5 \approx \66.67 .

Condition-Based Replacements

Consider now an item subjected to deterioration whose condition may be determined by inspection. Let the condition of this item be modeled by a stochastic process $\{X(t), t \geq 0\}$. This process may be continuous or discrete,

the latter being the case if the condition of the item may be classified in one of the finite number of states (see the section titled “Stochastic Processes” in this encyclopedia). Assume that an item is considered to be in a failed state when $X(t) > r_1$ and that a preventive replacement is performed when $r_1 \geq X(t) > r_2$, $r_1 > r_2 > 0$, which is often referred to as the item being in a marginal state. If $X(t) \leq r_2$, the item is in a functional state and no action is taken.

If the item is in a marginal state, there is an opportunity to replace the item preventively and at lower cost compared to a corrective replacement. Inspections are required to determine when the item is in a marginal state and possibly also to determine if an item has failed or not. This requirement differentiates this policy from an age-based replacement policy. Let $\tau > 0$ be the fixed time between inspections, such that $k\tau$, $k = 1, 2, \dots$, represents the time of the k th inspection. Also, each inspection entails a cost of $c_3 > 0$ monetary units. For inspections to be economically interesting, c_3 must be smaller than both c_1 and c_2 . Also, if failures are noticed immediately without the necessity of performing an inspection, the cost of a single inspection, followed by a preventive replacement, must be less than the cost of a corrective replacement. In this case, inspections are only useful if $c_3 < c_1 - c_2$. With these costs, the aim is to determine the optimal inspection interval τ^* , which minimizes the loss function $L(\tau)$. Such an optimal policy will present a balance between inspections, followed by a preventive replacement on the one side and a corrective replacement on the other side.

As in the age-based replacement model presented previously, each cycle in the condition-based replacement model ends with either a preventive or a corrective replacement. However, each cycle is now further partitioned at the times of one or more inspections. This becomes apparent in the cost function $c(k)$, which gives the costs incurred up to time $k\tau$:

$$c(k) = c_1 + (k - 1)c_3 \quad (8)$$

if $X((k - 1)\tau) \leq r_2$ and $X(k\tau) > r_1$ or

$$c(k) = c_2 + kc_3 \quad (9)$$

if $X((k - 1)\tau) \leq r_2$ and $r_1 \geq X(k\tau) > r_2$. Equation (8) is the sum of the cost of a corrective replacement and $k - 1$ inspections, which assumes that no inspection is required in the k th interval to determine that the item has failed. Equation (9) is the sum of a preventive replacement and k inspections. The influence of the inspections on this cost function is now obvious: a replacement (preventive or corrective) is only performed if no replacements were made during one of the $k - 1$ previous intervals. The following short notation is used for the probability of incurring the costs in Equations (8) and (9):

$$P_1(k, \tau) = \Pr\{X((k - 1)\tau) \leq r_2, X(k\tau) > r_1\}$$

and

$$P_2(k, \tau) = \Pr\{X((k - 1)\tau) \leq r_2, r_1 \geq X(k\tau) > r_2\}.$$

Using the expected average cost criterion in Equation (1) and the cost functions in Equations (8) and (9), the loss function is

$$\begin{aligned} L(\tau) = & \left\{ \sum_{k=1}^{\infty} [c_1 + (k - 1)c_3]P_1(k, \tau) \right. \\ & \left. + [c_2 + kc_3]P_2(k, \tau) \right\} \\ & \cdots \left\{ \sum_{k=1}^{\infty} E[T]P_1(k, \tau) + k\tau P_2(k, \tau) \right\}^{-1}, \end{aligned} \quad (10)$$

where the failure distribution is given by $F(t) = \Pr\{T \leq t\} = \Pr\{X(t) > r_1\}$. By dividing the loss function in Equation (10) by the cost of an inspection c_3 and rearranging the terms in the numerator, we obtain

$$\begin{aligned} & \sum_{k=1}^{\infty} \frac{c_1 - c_3}{c_3} P_1(k, \tau) + \frac{c_2}{c_3} P_2(k, \tau) \\ & + k[P_1(k, \tau) + P_2(k, \tau)] \end{aligned} \quad (11)$$

in the numerator. Like the age-based replacement model, this changes the value

at the minimum τ^* , but it does not change the location of the minimum. The result in Equation (11) shows that the location of the minimum depends on three things: the ratios $(c_1 - c_3)/c_3$ and c_2/c_3 and the expected number of inspections per cycle. The expected number of inspections per cycle depends on the threshold level for preventive maintenance,

$$\begin{aligned} &P_1(k, \tau) + P_2(k, \tau) \\ &= \Pr\{X((k-1)\tau) \leq r_2, X(k\tau) > r_2\}, \end{aligned}$$

therefore the preventive replacement threshold r_2 is also a parameter, which may be adjusted in order to obtain an optimal replacement policy.

As mentioned earlier, if a failure is only observed by inspection, the cost function $c(k)$ must include a penalty for each time unit that the item is left in a failed state. Otherwise the optimal policy would be to not inspect at all, that is, $\tau^* = \infty$, since this would make the expected cycle length infinitely large, whereas the expected costs per cycle remain finite. If c_4 is the cost of a nonfunctional item per time unit, then the cost function in the case of a preventive replacement in Equation (8) is given by

$$c(k) = c_1 + kc_3 + \int_{t=(k-1)\tau}^{k\tau} (k\tau - t)c_4 dF(t).$$

The denominator in Equation (10) simplifies to

$$\sum_{k=1}^{\infty} k\tau [P_1(k, \tau) + P_2(k, \tau)],$$

since the item is always replaced at the time of an inspection.

There are many variations on the basic model for condition-based maintenance. Obviously there is the formulation of the loss function in Equation (10) using discounted costs, but there are also many different types of stochastic processes that have been used to model the uncertain deterioration over time, represented here by $X(t)$. A minimum requirement for the model presented here is that $X(t)$ is monotonically increasing, such that $X(t_2) \geq X(t_1)$ for all $t_2 \geq t_1$.

For continuous types of deterioration, the gamma process is a good candidate. The gamma process is a continuous-time stochastic process with independent gamma-distributed increments. It also belongs to the family of Lévy processes. See Ref. 19 for a broad review of the application of gamma processes to maintenance optimization. Such a gamma process is applied by Jia and Christer [20] in a condition-based replacement model, which they extended to include the time of the first inspection, τ_1 as a separate decision variable. Such a model can be useful in situations in which the rate of deterioration proceeds slowly after the item is taken into service and then gradually increases. The optimal policy may then be the one in which the first inspection is followed by more frequent periodic inspections. A condition-based replacement policy may also be determined for discrete types of deterioration using a Markov chain for $X(t)$ [21] or in situations where inspections are not able to determine the exact state of deterioration $X(t)$ [22].

OPTIMAL RISK MITIGATION AND RISK-TAKING

CHRIS CHAPMAN

IAN HARWOOD

School of Management,
University of Southampton,
Southampton, UK

Risk mitigation and risk-taking is commonly approached in a different manner in different areas of application—operations management, project planning and strategy formation for example. To some extent these differences reflect different dominant background frameworks—decision analysis, portfolio selection, or scenario building for example. In any decision-making context, optimal risk mitigation and risk-taking demands an optimal set of working assumptions within an optimal set of framing assumptions. Working assumptions are context and application specific assumptions of convenience—robust simplifications to save effort and time which are appropriate to the circumstances. Framing assumptions include what is meant by overall optimality, what “risk” means, and an understanding of the purposes of risk management [1]. These assumptions are impacted by phenomena such as “problem framing,” “outcome history,” and “judgmental bias” [2].

The distinction between a local optimum and a global optimum is widely understood in contexts like mathematical programming—for a local optimization process to be consistent with a broader global optimum, conditions associated with global optimization have to be met. The overall optimization of interest here is a generalization of this notion, a form of universal optimization that addresses the nature, costs, and benefits of alternative decision-making processes as well as the nature, costs, and benefits of the decisions made.

To facilitate overall optimization in practical terms, optimal framing assumptions must be common for all application areas. Further, the basic tool kit must be portable, flexible,

and integrated—a modern approach to practical ORMS requires a multimethod approach with compatible components [3].

The framing assumptions and tools used in this article were initially developed for project risk management, where they have been used successfully in practice since the mid-1970s [4]. They have also been used successfully in many of the other areas covered in the section titled “Risk Analysis Applications” in this encyclopedia and could be used in the others [5]. They embrace the issues discussed in the rest of the section titled “Risk Analysis” plus some parts of the sections titled “Markov Decision Processes (MDPs)” and “Decision Analysis” in this encyclopedia.

The following section illustrates simple working assumptions within a general framework plus a simple version of a basic tool recommended for making choices. A more complex version of this basic tool is then illustrated together with its companion tool. Risk-taking at corporate levels and linked behavioral issues are considered next. Working assumptions when starting an analysis are then considered and linked to bottom-up strategy formation. This section also links alternative frameworks which may be compatible. Consideration of top-down strategy formation completes an introductory overview of the key issues.

A SIMPLE OPTION CHOICE EXAMPLE

A simple example illustrates a recommended basic tool for making choices in a form initially developed for IBM UK for bidding purposes [5, Chapter 3]. It also illustrates other simple working assumptions within a general framework, and how more complex working assumptions can be addressed as necessary.

The approach suggested uses a generalization of the “uncertainty” concept employed by modern decision analysis, a generalization of the “risk” concept employed by modern portfolio theory, and synthesizing these two usually disparate perspectives. It assumes “measured” uncertainty and risk

can be portrayed by cumulative probability distributions, but there is no direct metric or proxy for either, and there is no need to specify utility curves or functions. It assumes that more than one objective is usually relevant and some objectives may involve an attribute that is not measurable in a useful sense.

The single photocopier in a busy office failed terminally. The office manager had to replace it quickly, and justify his choice of replacement later. He could obtain the same machine from the same supplier on a comparable contract. The contract cost for a minimum number of years was a rental charge per month plus a maintenance charge per copy. The only source of uncertainty associated with contract cost over the minimum number of years was the number of copies needed. The option A line in Fig. 1 portrays the office manager's estimate of the contract cost per year of this choice, assuming a linear cumulative probability distribution, corresponding to a uniform probability density function. Figure 1 uses the absolute minimum and maximum points " a_1 " and " a_2 " for portrayal simplicity, and these values can be used for estimation purposes. However, using 10 and 90 percentile value estimates to optimize the elimination of bias is recommended. In either case it is important to recognize that the true curve will be nonlinear and asymmetric.

Alternative suppliers offering comparable machines on the same contractual basis were evaluated using the same 10 and 90 percentile estimates, portrayed as lines B and C in Fig. 1.

Assuming minimizing contract cost was the primary objective, and making this assumption clear, the office manager argued that A was the risk efficient choice (its expected cost was the lowest and it involved less risk), because the option A line was entirely to the left of the B and C lines. As the option A machine was marginally faster than B or C, option A dominated when considering this secondary objective too. Had this not been the case, employee time lost waiting for copies might have been estimated and converted to an opportunity cost, followed by aggregation to a single cost attribute. Alternatively, any important secondary objectives might have been considered using separate graphs in Fig. 1 form, or a simple judgment made about whether the gap between (Fig. 1) primary objective lines was large enough to more than counterbalance secondary considerations.

As the office manager knew that the color and design style of the current supplier's products was consistent with the corporate consensuses of an optimal house style, this third-order objective was not an issue either. Had this not been the case, the gap between the curves would have to be evaluated by the relevant person or group in terms of trade-offs between nonmeasurable objectives as well as measurable objectives. An optimal approach in the general optimum sense uses simple dominance tests for additional objectives unless more sophisticated approaches look useful [5].

Had the option A machine been unavailable in a feasible time frame, the B option

Figure 1. A simple example of an option choice graph.

would not dominate C in the risk efficient sense, indicted by the way the lines cross. However, the lower expected cost of B justifies the marginal increase in rental cost risk—at a corporate level this kind of additional variation should be regarded as just “noise.” This alternative starting position would also have to be tested in terms of additional objectives, measurable or nonmeasurable.

Had B or C seemed preferred choices because A was not available in a feasible time frame, reliability risk and risk associated with a new supplier who might not deal effectively with reliability or other issues would need care. Risk to the company and risk to the office manager might need separate consideration by the office manager—the office manager’s reputation might suffer from a highly visible mistake, perhaps costing the office manager their job if times were tough. Optimal mitigation of these risks might involve exploring more general working assumptions, like borrowing a copier from the existing supplier until A is available, a simple example of a reformulation of the choices available to deal with emerging concerns in a general framework.

More complex problem formulation and reformulation issues will be considered later, but this example illustrates a flexible general framework that can address multiple attributes (some not measurable), risk that is not limited to downside variability of measured attributes, and risk perceived differently by different parties.

This approach assumes one attribute per objective, but a multiple criteria approach to each attribute, involving expected outcome and risk. Risk is not measured by a single criterion like variance—it is depicted graphically by cumulative probability distributions. Comparing the B and C options graphically and choosing one implies an underlying decision function approximation to preference functions which addresses trade-offs between expected outcome and associated risk exists, but it does not require its specification or agreement between different relevant parties. Similarly, choices involving more than

one attribute imply the existence of appropriate decision function approximations to preference functions, which addresses trade-offs between attributes, but it does not require their specification or agreement between relevant parties.

“Risk efficiency” (a minimum level of risk for any given level of expected outcome for any attribute of interest including nonmeasurable attributes) in terms of all relevant attributes as a basis for optimal trade-offs between all relevant attributes is at the core of the underlying framework adopted here, the key framing assumption. A significant generalization of Markowitz’s notion [6] of risk efficiency is involved. One aspect of this generalization is recognizing that the measures of skew and other moments may be relevant, not just mean and variance, addressed by working directly with cumulative probability distributions. The other is considering all relevant attributes, using Fig. 1 equivalents for all measurable attributes. Nonmeasurable attributes like optimal house style and the office manager’s reputation may require considerations too, as may attributes not worth measuring, like the reliability of other machines and suppliers. Distinguishing between risk to the organization and risk to the office manager is important. Links like the effect on the office manager’s reputation of a commitment to a poor machine and supplier are important.

Working assumptions not addressed for robustness associated with this analysis include no need to look beyond the minimum rental contract period, or decompose average variability per annum within this period, or estimate Fig. 1 using more sophisticated probability distributions. Judgments about value, value trade-offs, and associated uncertainty, including process as well as option issues are core concerns explicitly addressed in this example, via a flexible approach to working assumptions suitable for the context. No concerns of potential importance are overlooked, even if they cannot be measured (like optimal house style or office manager reputation), or measurement is not practical (like the reliability of a new supplier).

Figure 2. A North Sea project example of an option choice graph.

MORE COMPLEX OPTION CHOICE CURVES USED FOR RISK MITIGATION OPTIMIZATION

A more complex example illustrates a more sophisticated version of the same tool for making choices as it was used by BP International in the 1970s for the Magnus project, a £1000 million North Sea oil project. It also illustrates more sophisticated assumptions about the role of risk management.

Figure 2 was shown to the BP main board to illustrate why one risk mitigation measure developed via a new project risk management process [7] would more than pay for the application of that process. This was the basis of a case for using this new process to save money, perhaps £100 for every £1 invested in the process. This saving would be in addition to meeting the original objective of the process from a board perspective, providing the basis for time and cost estimates that were unbiased; on average BP could bring in projects on time and on cost using the new process, later demonstrated statistically.

The base plan approach to “hook-up”—linking the offshore pipeline to the production platform once both were in place—assumed the use of a barge with a 1.6-m nominal maximum wave height capability. The 1.6-m barge was shown to be sensible if this activity took place in August as planned, and August was shown to be a sensible target plan. However, the cumulative effect of delays to all earlier activities were shown to lead to likely delays to the start date, with about a 10%

chance of a failure to complete before winter set in, with £100 million consequences, portrayed by the long right-hand tail of the 1.6-m barge curve in Fig. 2. The 3-m barge was a mitigation measure to address this risk. It virtually eliminated the chance of failing to complete before winter, and its expected cost was shown to be about £5 million less, despite a much higher cost per day. Some reduction in expected cost was associated with fewer days being required, but eliminating the 10% chance of an extra £100 million was crucial. This simultaneous reduction in expected cost and risk—an improvement in risk efficiency—is portrayed in Fig. 2 by the more vertical 3-m curve with a lower expected cost. The 1.6-m barge had a 70% chance of being cheaper, indicated by point “a,” but “b” is to the left of “c.” On the basis of a discussion of Fig. 2, the board mandated the underlying process worldwide for all large or sensitive projects, because the board was convinced that the increase in project risk efficiency would more than pay for the process, the basic rationale for risk management based on the recommended framing assumptions.

LAYERED CONTRIBUTION GRAPHS TO PORTRAY HOW UNCERTAINTY ACCUMULATES

Before considering the cost implications of the completion of a late activity like “hook-up,” sources of uncertainty and associated

Figure 3. A North Sea project example of a layered contribution graph. Probability curves show the cumulative effect of the following issues: 1, yard not available, or mobilization delays; 2, construction problems/adverse weather; 3, subcontracted nodes' delivery delays; 4, material delivery delays; 5, industrial disputes; and 6, delayed award of fabrication contract.

mitigation had to be addressed for all earlier activities and this had to be linked in a nested structure, which reflected knock-on relationships and dependences. The choice curves in Fig. 2 measure composite sources of uncertainty, which needed decomposition in an optimal manner. Figure 3 illustrates an activity level portrayal of completion date sources of uncertainty and associated mitigation measures specific to that source within an activity, in this case the fabrication of the “jacket” (the steel structure forming the basis of the platform used to produce oil).

Curve 1 is the cumulative probability distribution associated with source of uncertainty 1 given any specific mitigation measures for that source. Curves 2–6 successively add comparable cumulative probability distributions for sources 2–6. Curve 6 provides the overall total, and curves 1–6 show the contribution of that component

via the successive gaps—5 is the biggest, 2 the smallest.

To compute these curves using a standard Monte Carlo simulation package assuming independence between sources of uncertainty, $X_1 - X_6$ could define the outcomes of samples from each of the six source of uncertainty distributions, with $X_7 = X_1 + X_2$, $X_8 = X_7 + X_3$, and so on to $X_{11} = X_{10} + X_9$. Then curve 1 is defined by X_1 , curve 2 is defined by X_7 , and so on with curve 6 defined by X_{11} . That is, n sources require $n - 1$ composites instead of just one overall composite to provide all n curves. Dependence specifications have to be defined in terms of preceding composite components for sources 3–6—source 2 dependence can be defined in relation to source 1. Independence is a very special case of the implied separability conditions [5, Chapter 10].

In this case, the ordering of sources 5 and 6 reflects mitigation discussions. Source 6

could be eliminated by senior management action fairly simply—the first mitigation measure discussed was early award of the fabrication contract. This still leaves an uncomfortable situation. Source 5 could be almost eliminated, by more complex management action, which might impact source 6. Source 5, industrial disputes, was initially sized subjectively, but its size led to data analysis, which suggested that industrial disputes were the result of a “feast or famine” environment for platform constructors. The only viable mitigation identified was collaboration with other oil companies to smooth the flow of work. This should lower contracted prices as well as the chance of industrial disputes—an example of an opportunity discovered while looking for risk efficient responses to overall uncertainty. If the uncertainty portrayed in Fig. 3 for both 5 and 6 were effectively eliminated by mitigation in this way, curve 4 becomes an acceptable picture within this activity.

Curve 1 is a composite of two sources of uncertainty, both assessed in relation to optimal mitigation measures prior to the estimation of curve 1. For example, “yard not available” might have arisen because another company’s jacket is not finished by the contracted time to start BP’s jacket, and the yard (a dry dock) cannot float it out until it is finished. The first choice response was “find an adjacent site and start stockpiling steel to cope with a short delay.” This involved a secondary source of uncertainty—“a long delay may be involved.” In this case, optimal mitigation shifts to “find another yard.” The secondary source of uncertainty here is “there may be none available.” “Accept a long delay” then becomes the only available choice. Figure 3 shows six sources of uncertainty at this activity level because more curves make these layered contribution graphs too complex to read easily. However, each curve can involve a lower level structure, and each of these can be further decomposed. The first source on an activity level graph is often “delays caused by earlier activities,” a composite built up by working through the activity network. The second source is often a composite like “production problems” in Fig. 3, a composite of sources

of uncertainty not deemed worthy of separate pre-emptive analysis. Judging how far to decompose uncertainty for a cost-effective understanding of optimal mitigation, as well as unbiased estimates, is the target of an optimal process which is discussed later.

Each activity needs to be addressed in this manner, managing mitigation specific to each source of uncertainty. Further, “general” mitigation measures, which can address accumulated uncertainty from many sources, including knock-on effects, require consideration at a number of levels. The 3-m barge option is one example of a general response. Another example is a second or third shift for the pipe coating operation—it would mitigate delays specific to pipe coating and earlier difficulties.

Decomposition of activity uncertainty can include the use of Markovian processes, to optimize mitigation measures on a time period by time period basis.

Building up an understanding of duration driven uncertainty and the impact of mitigation measures activity by activity in this way leads to the ability to portray related costs, including the implications of a mitigation measure like that portrayed by Fig. 2. Underlying both Fig. 2 curves is a nested set of Fig. 3 format curves. Further, any choice of mitigation options during the build-up can use the Fig. 2 format.

An optimal approach to risk mitigation for complex projects requiring detailed proactive risk mitigation demands this approach for projects being shaped at an implementation and delivery strategy shaping stage, as demonstrated in the 1970s, and many times subsequently. By the end of the 1970s, it had become clear that risk efficiency and unbiased estimates are not the only benefits, but processes working within the same framing assumptions can also meet a number of additional objectives, which are important [4, Chapter 2 and 5]. The very simple structure demonstrated by Fig. 1, perhaps supported by linear versions of Fig. 3, uses simpler working assumptions while drawing on the same general framing assumptions. All projects and all operations management choices need an optimal level of simplicity/complexity in

terms of these working assumptions, generally between that illustrated by Figs 1 and 2, drawing on the same framing assumptions. All projects and all operations management also have to adapt their risk management objectives to the context and application in an optimal manner.

A framing assumption illustrated by the role of Fig. 3 is the need to decompose measured overall uncertainty and associated risk as and when necessary into intermediate level composites as well as base level sources of uncertainty in an optimized structured manner, using the structure to deal with dependence and knock-on effects. Figure 3 portrays the way the measured uncertainty accumulates, providing built-in sensitivity analysis, an optimal approach to understanding how what has been decomposed fits together.

Another framing assumption is the use of Fig. 2 to assess alternative risk mitigation measures as well as basic choices like those addressed in Fig. 1.

Working assumptions associated with Figs 2 and 3 include the need to look at the possible delay to completing “hook-up,” and its cost implications in terms of component composites at a reasonably detailed level, considering the impact of mitigation measures in the process, and dependence. Some mitigation measures operate at the base level, some at the overall uncertainty level, and others at the intermediate levels. Some are reactive, some are proactive. Some are just fixes for threats, but others are

opportunities. Dependence may take a range of simple statistical and complex causal forms.

In the context of this example, the multiple attribute and non-measurable attribute and multiple party complications considered in the last section were not relevant—in this sense the consideration of risk efficient choices was relatively simple for BP.

In the context of Fig. 1, no Fig. 3 equivalent was optimal, but if both contract cost as measured and opportunity cost associated with employee time were relevant, a Fig. 3 curve equivalent could be very important. In some contexts, simple linear versions of Fig. 3 or spreadsheet equivalents may be optimal.

An overall optimum implies the need to always search for risk efficiency at an appropriate level of detail, understanding how the detail fits together with a flexible set of working assumptions suitable for the context.

RISK-TAKING AT CORPORATE LEVELS AND LINKED BEHAVIORAL IMPLICATIONS

During the 1990s, IBM UK undertook a culture change program involving a two-day “forum” run about 40 times to cover all senior staff. It used a discussion of Fig. 2 followed by a discussion of Fig. 4 as its starting position.

Having explained the implications of Fig. 2, it was pointed out that slightly different numbers might have shifted the 3-m curve to the right as shown in Fig. 4. Point “a” now suggests that the 1.6-m barge

Figure 4. Shifting the 3-m curve on Fig. 2 to the right.

has an 80% chance of being cheaper. Of crucial importance, the reversal of points “b” and “c” suggests that the expected cost of the 3-m barge is now about £5 million more than the expected cost of the 1.6-m barge. However, the long tail for the 1.6-m barge implies much more risk, still comparable to a 10% chance of an extra £100 million. The key question is should this extra risk be taken?

A basic Markowitz approach implies that both options are risk efficient and the choice is a matter of decision-taker preference—the board needs to use an implied decision function based on the preferences of individual members to make a choice without necessarily agreeing about preferences. The position here, and the point of the IBM story, is that the choice should be a matter of corporate “risk appetite” [8], determined via risk efficient assessment of all projects and other corporate operations. Knowing some £1000 million projects could double in cost, BP used risk sharing partnerships with other oil companies to share big project risk. Having gone to this trouble and expense it was clear that it did not make sense to add £5 million to the expected cost to avoid a £100 million risk. BP would take an “enlightened gamble” in a case like this, to aggressively maximize profit within their risk appetite. IBM had to identify a suitable corporate risk appetite and persuade all decision-takers to aggressively take risk to remain competitive and avoid the risk of IBM going out of business because IBM was too expensive. Taking risk up to the limit of corporate risk appetite involves “enlightened gambles” illustrated by the Fig. 4 situation.

Once Figs 2 and 4 were understood in terms of the crucial role of enlightened gambles, “enlightened caution” was discussed. It was pointed out that the actual hook-up took place in late October, the weather was good, and it was evident after the fact that BP could have got away with the 1.6-m barge. Given the analysis associated with Fig. 2, it was clear that the project manager had done a good job, made the right barge choice, and been lucky with the weather. It was also clear that had no analysis been done and a 3-m barge chosen, the project manager would

have been accused of wasting money. Further, it was clear that if no analysis of this kind was available, any experienced project manager would see the 1.6-m barge as the best choice in terms of their career interests, even though it is a risk inefficient, “unenlightened gamble” in corporate terms. “Enlightened caution” involves avoiding risk inefficient gambles.

Optimal risk-taking has to address corporate risk appetite in terms of a risk efficient approach to overall corporate risk. It has to make the formal analysis approach discussed here available to support high profile enlightened gambles and caution. And it has to ensure that the concepts are used informally for all other choices at all levels of projects and operations decisions. In effect, it has to distinguish between good luck and good management, bad luck and bad management, for all decision making. This involves a culture change for many organizations—formal analysis processes and tools are only part of what is needed.

IBM recognized this and directly managed a culture change, introducing risk management tools and processes as part of a culture change. Moving from a risk-averse culture to a risk-taking culture was the key goal, with a view to significantly improving profitability. An appropriate corporate risk appetite and linked management of individual behavior is a central issue for most organizations.

PROJECT AND OPERATIONS CHOICES IMPACTING STRATEGY AND OTHER FRAMEWORKS

The basic Markowitz mean-variance approach to portfolio selection [6] as generalized earlier in this article needs to be linked to conventional decision analysis [9] and scenario building [10] frameworks. This discussion also needs linking to a generalisation of the problem formulation discussion initiated earlier and bottom-up strategy formation. Consider an example.

Stan, the sole owner of a UK firm, which manufactured injection-molded plastic point-of-sale displays, wanted to consider buying a new type of injection molding machine, which

Table 1. Payoff Matrix for a Simple Machine Choice Example

Action: Size of Machine	Event: Market Growth				Criteria: More?	
	Zero	Poor	Moderate	Good	Expected Payoff	Standard Deviation
No machine	0	0	0	0	0.0	0.0
Small	−1	3	2	1	1.6	1.5
Medium	−2	2	5	2	2.1	2.4
Large	−4	−2	2	8	0.3	3.9
Probabilities	0.20	0.35	0.30	0.15		

could produce a completely new type of display product. Three different production rate capacity “sizes” of machines were available. All were highly automated, sophisticated, and expensive. There were differences in associated technologies, but Stan did not see these as important. The new point-of-sale products might compete with current products, but they would probably complement them, and manufacturing them would probably strengthen Stan’s overall marketing position. Space for any of the new machines was available, staffing implications for all three raised no obvious difficulties, and the key issue from Stan’s perspective was matching the size of machine to the size of the market, because the size of the market was very uncertain.

Table 1 is a classic payoff matrix portrayal of Stan’s choices, summarized from an extended discussion in Ref. 5, Chapter 9.

Table 1 involves four mutually exclusive action choices—a large, medium, or small machine plus the no machine option. Table 1 also involves a scenario or event breakdown of the uncertain market size growth—zero, poor, moderate, and good, with probabilities for each, assumed to be common to all four actions. Further, payoffs for each are shown in £100,000 units, an estimate of the net present value (NPV) of additional future profits after costs. Two criteria are also shown, expected payoff and standard deviation. A very relevant question is posed—more criteria?

If maximizing expected payoff is the only criteria, the optimal choice is the medium machine. If a basic Markowitz approach is adopted, standard deviation is a simpler measure of risk than variance, and Table 1 indicates standard deviations. In these terms the small and medium choices plus the no plant

are risk efficient—only the large plant can be rejected as risk inefficient.

The basic mean-variance or mean-standard deviation approach does not yield a unique choice. This is a conventional decision analysis argument for ignoring a mean-variance approach. If risk may matter, this is sometimes the rationale for moving to an expected utility approach at this point, normally without actually considering the mean-variance alternative or other alternatives.

However, say we move directly from Table 1 to Fig. 5, adopting the option choice format of Figs 1 and 2 to portray the information in Table 1.

Figure 5 takes the discrete point value estimates of Table 1 literally. For example, the large machine has a minimum value of −4 associated with a 0.2 probability, and the next higher value is −2, so the cumulative probability curve rises from 0 to 0.2 at a payoff of −4, then moves horizontally to a payoff of −2. Figure 5 uses a dashed line for the large machine option because it is not risk efficient. Figure 5 also uses a bolder solid line for the medium choice because it is arguably the best choice unless Stan cannot afford to take the additional risk. This additional risk is portrayed by the dashed line relative to the bold solid line after they cross at a cumulative probability of 0.85—risk is not measured by a single metric, but the difference in risk associated with alternative choices is clearly portrayed in terms defined by whatever probability distribution working assumptions are appropriate.

It will be obvious that the true distributions approximated by the Fig. 5 model are smoother. It will also be obvious that Fig. 5 curves are not very easy to read, because

Figure 5. Plotting the cumulative distributions from Table 1.

of their angular nature. Indeed, the position taken here is the intermediate scenarios are not all that useful, and a better use of time and effort to this point is simple $p_{\min}$ and $p_{\max}$ scenarios for each option to define linear cumulative distributions. For present purposes, the Table 1 minimum and maximum values for each choice would serve as these $p_{\min}$ and $p_{\max}$ P10 and P90 approximations, yielding Fig. 6.

The P10 and P90 dotted lines were used to plot these simple linear cumulative probability distributions, for example, the large machine P10 was assumed to be -4 , with a

P90 of 8. Expected values can now be taken from the P50 dotted line, for example, the large machine P50 is 2 (the average of -4 and $+8$).

Apart from the relative ease of interpretation, an obvious difference is the large machine is now a risk efficient choice, with an increase in expected value from 0.3 to 2.0, while the medium and small machines both have lower expected values than on Table 1. All four options are now shown with the same weight solid line—none are risk inefficient and there is no obvious default choice. Advocates of conventional decision

Figure 6. Simplifying the cumulative distributions from Table 1.

Table 2. Simple Example Alternative to the Table 1 Payoff Matrix

Size of Machine	Key Uncertainty Source: Market Growth		Expected NPV
	$p_{\min}$	$p_{\max}$	
No machine	0	0	0
Small	-1	3	1
Medium	-2	5	1.5
Large	-4	8	2

analysis might argue that information has been lost—Fig. 6 almost harps back to a classic “decision making under uncertainty” paradigm with the assumption that each scenario is equally likely—so the move from Table 1 and Figs 5 and 6 might be seen as counterproductive, moving in the wrong direction. The view taken here involves a series of counterarguments, but it might start by arguing that Table 2 is an effective simplification of Table 1, which is all that is needed to obtain Fig. 6. That is Table 2 is a better place to start, moving directly to Fig. 6. Table 1 involves additional information in an unduly constrained form, which makes Fig. 5 less helpful, so Table 1 is not as good a place to start.

One part of the reason Table 2 is a better place to start is the “lost information” associated with Table 1 is distorted by the assumption that all probabilities are common to all action choices—in practice a large machine will involve a lower unit cost, which will tend to create a larger market. This distortion is avoided if Table 1 is simplified to Table 2 as a basis for Fig. 6.

A second reason is empirical experience with scenario building approaches [10] suggests that two scenarios representing plausible extremes usually more effective than three or more, because more attention to what underlies two plausible extremes is time better spent than additional attention to central scenarios.

A third reason is empirical experience with risk management in various contexts [5] suggests that a first pass analysis which provides a very quick overview of the scale of all sources of uncertainty before detailed examination of what seems to matter on later

passes is the only efficient and effective way to proceed.

A fourth reason is the need to avoid closing down the options via an expected utility theory approach, which may be moving in the wrong direction. What may be needed is opening up the options via more clarity about what matters. Clues about what matters are often discovered by exploring important working assumptions. Working assumptions need identification, testing, and possible relaxation to yield these clues—what many decision sciences call “robustness analysis,” taking different forms in practice depending upon the school of thought. Consider illustrative examples of this approach, taken from Ref. 5, Chapter 9.

At a fairly fundamental level of analysis, we can start by recognizing that the real risk for Stan may not be variations in additional NPV in the terms measured thus far—it may be the threat to his current local market dominance if he cannot offer the new products at competitive prices. His current local market dominance may be the foundation of Stan’s business. Any threat to this dominance may be crucial. This is an issue, which the “no plant” payoff of zero for all market events clearly ignores, implicitly the case for the other options. The best defense for Stan may be attack, selling the new type of product to protect his overall market position with the most aggressive pricing feasible if necessary. Given this insight, it may be obvious that “no machine” as defined by Table 1 is not a viable choice, but neither are any of the other mismatches between machine size and market size. Indeed, it should become obvious that the four options of Tables 1 and 2 are not mutually exclusive, and it may be possible to buy capacity on someone else’s machine or sell capacity on a machine which is too big for the current point-of-sale display market. This insight, in turn, might suggest buying capacity until the potential market size becomes better defined, then moving to an appropriate machine or machines, with a view to using any spare capacity in some other way.

At an intermediate level of sophistication, uncertainty associated with competitors and feasible market prices might be explored,

using layered source of uncertainty format graphs like Figs 1 and 2 to break down revenue and cost sources of uncertainty, possibly in a nested structure.

At a more sophisticated level of analysis, this breakdown might be related to a variant of multiple attribute value theory (MAVT) approaches, considering the desirable and undesirable attributes of the different machines. This might reveal that the large machine involves leading edge advanced technology, with patents in place and excellent performance with guarantees from a high reputation manufacturer. The medium and small machines might be relatively old fashioned and unreliable. This might imply high resale values and low depreciation for the large machine. All these features in conjunction with the lowest variable cost per unit produced and the lowest purchase cost per unit of production capability may make competing against anyone with a large machine in any relevant market very difficult—the real threat Stan needs to avoid. Crucially, the large machine manufacturer may be non-EU, with limited EU penetration, and have no UK sales presence—Stan might be able to negotiate a UK franchise for sales of the large machine on the back of purchasing one which could be used as a demonstrator with trial capacity for sale. Best of all—Stan might really enjoy the opportunities and such a move might provide—most good entrepreneurs are motivated by the “fun” involved in this kind of opportunity.

The [5, Chapter 9] discussion leads to this conclusion considering a range of tools which might generate this kind of insight. Approaches discussed include variants of MAVT as advocated by Belton [11] and others. Multiple attribute utility theory (MAUT) as commonly linked to decision analysis by Keeney and Raiffa [12] and others is rejected because embedding risk in the metric used for each attribute via a utility function is not a suitable working assumption in many circumstances—obviously the case when non-measurable attributes are involved or more than one person is involved and agreement about preferences is not feasible. More generally, transparency is lost, which the

discussion of curves like those of Figs 1–4 and 6 enhances.

Some advocates of MAUT may see this and the rest of this section as contentious. A structured case to persuade them to alter their framing or favorite working assumptions is beyond the scope of this article, but it is important for all readers to understand that the kind of generalization of Markowitz’s risk efficiency ideas advocated earlier is not compatible with expected utility assumptions. As argued by Williams [3], practical ORMS requires compatible multimethodologies; so, choices need to be made about what features of conventional decision analysis we want to use in an integrated manner with appropriate features of conventional portfolio and scenario analysis. Very simple versions of basic Markowitz models and expected utility approaches are comparable, but not the generalizations discussed earlier.

A key linked point is the need to reject a conventional decision analysis payoff matrix, like Table 1, as a place to start when analyzing decisions in practice, if the associated working assumptions are not optimal for the choice being considered. The Table 1 framework reflects the conventional decision analysis starting point for framing assumptions—selecting a unique optimum from a predefined set of mutually exclusive options evaluated in terms of three or more discrete event scenarios common to all options using restrictive framing assumptions about risk and value trade-offs. A better place to start may be a simple table of options like that of Table 2, and graphs like those of Fig. 6, employing the option choice format of Figs 1 and 2. Each of the options in the Table 2 format can be considered a potential “project” or “operation” strategy, and the integration of two or more of these potential strategies can be viewed as a program or portfolio of projects and operations defining the development of an emerging strategy. All the analysis possibilities underlying layered source of uncertainty graphs like Fig. 3 as used by BP and others are part of the possibilities available from this starting position, plus a range of other exploratory approaches, like MAVT, in the very general framework discussed in relation to Fig. 1.

The focus of an approach providing overall optimality is seeking clarity about what really matters in an effective and efficient manner. Robustness analysis is a key part of this—understanding the role and importance of working assumptions. Table 1 and a conventional approach to decision analysis is a dead-end relative to Table 2 and an approach that opens up the options.

Another key point here is the compatibility of the Table 2 and Fig. 6 approach to decision analysis extended to decision trees as a basis for multiple stage decision choices and value of information concepts. Each decision node in any decision tree can be modeled in these terms. Multiple level decision trees cannot be reduced as simply—conditional choices may need to be addressed considering all branches of the tree—but in practice, this is a price worth paying for the clarity provided by avoiding restrictive assumptions. At any level in a decision tree choices are not mutually exclusive or uniquely defined, and their definition can be better shaped if it looks like it might pay to do so.

Other frameworks not mentioned here also need integration with respect to useful compatible features. Portfolio selection, decision analysis, and scenario building are simply the three key starting positions for addressing most risk mitigation and risk-taking in practice. Examples include influence diagramming to address dependencies and systems dynamics modeling to consider forensic risk management [3].

TOP-DOWN STRATEGY FORMATION

Some strategy formation can be driven bottom-up as illustrated in the last section, but top-down frameworks are also needed in many contexts. Consider another example.

In the 1990s, Ontario Hydro developed a 25-year strategic plan that included a significant development of their portfolio of nuclear power stations. Their proposed strategy might have been a good idea, but its presentation framework had a fundamental difficulty—an inappropriate view of risk and optimal mitigation of that risk. The plan was withdrawn when this difficulty became obvious.

An electric utility like Ontario Hydro needs to manage two kinds of risk of interest here in quite different ways, explored in detail in a report to the commission considering it and subsequent publications [5, Chapter 11], outlined here.

One is risk associated with the utility's inability to forecast which sources of electric power will be cheapest in 25 years time—renewable sources of various kinds, nuclear, oil, gas, and so on. Legislative issues and political pressures are involved as well as market forces. The only way to optimize in terms of this risk requires a generalized portfolio selection approach—most utilities cannot afford to “put all their eggs in one basket.” Optimal risk mitigation is virtually by definition a portfolio selection problem addressing efficient diversification—aiming for a position at the 25-year planning horizon which involves that mix of sources of electric power which minimizes the risk for any given expected cost, and choosing a level of risk that is appropriate for the organization.

A utility can change their view of the optimal mix to aim for as time evolves and current views of expected values and associated risk change. But it has to move toward that target mix as new units are added to meet rising demand and the need to retire existing units. Assessing the gap between the current target and the current position is the basis for deciding the sequence of new units to be added.

A second risk is introducing new units in the selected sequence too soon or too late—a timing issue best considered in the generalized decision analysis framework discussed earlier.

Most organizations have to blend top-down analysis of this kind with bottom-up analysis of the kind discussed in the previous section to achieve an overall optimum in their approach to strategy formation. Their diversification issues may be across product markets, input suppliers or areas of research—but diversification is a common risk mitigation issue.

Stress testing key assumptions may also involve top-down strategic consideration of scenario analysis, as developed by Shell [10]

to test corporate strategy against very high or low oil price scenarios. The relevant scenarios may include external circumstances which are not directly measurable, like a collapse of interbank lending because of a loss of trust if the organization is dependent upon this kind of finance, or a collapse of broader markets, or major political events.

Overall integration also has to address issues like the role of discounting in decision making [13 and 5, Chapter 8], safety [5, chapter 7] and internal and external contracts [14 and 5, Chapters 5 and 6].

Overall optimization requires overall integration of all this decision making, using compatible framing assumptions.

CONCLUSION

Optimal risk mitigation and risk-taking requires an optimal set of framing assumptions for all organizational contexts and optimal working assumptions specific to each context and application developed on an iterative basis as analysis progresses and insight is gained—ORMS processes in general are learning processes, which do not pursue a “right first time” policy. Simple tools like those illustrated by Fig. 1 may suffice, but the framework employed must be general, and an optimal approach usually requires a level of sophistication somewhere between that illustrated by Fig. 1 and that illustrated by Figs 2 and 3. Even the Fig. 1 analysis was within a sophisticated general framework, addressing subtle issues not relevant to the discussions on Figs 2 and 3. Understanding and exploiting the possibilities underlying Fig. 4 requires attention to behavioral issues as well as appropriate tools and processes. Problem formulation issues and the links between strategy formulation and more detailed operations and project management choices is complex, but they can be addressed within the same framing assumption set, as illustrated in the last two sections. Proper resolution of potential controversy associated with this topic in the context of Figs 5 and 6 is beyond the scope of this article, but appreciation of the need for an integrated set of compatible framing assumptions and tools

is essential for sound ORMS practice [3]. A somewhat different controversy, for the same basic reason, is addressed in Refs 1 and 13.

OPTIMIZATION AND DECISION SCIENCES (ITALY)

ROBERTO TADEI
Politecnico di Torino,
Corso Duca degli
Abruzzi, Torino, Italy

AIRO, Associazione Italiana di Ricerca Operativa—Italian Operations Research Society—Optimization and Decision Sciences, is a purposeful scientific organization comprising approximately 400 researchers as well as several University departments, companies, and other bodies that are interested in operations research (OR) in Italy. AIRO also has many foreign members. In this brief article, we want to outline the most important moments of the story of our association.

AIRO was founded on 20 April 1961 in Rome, at ISTAT (Istituto Centrale di Statistica—Italian Institute of Statistics) headquarters, owing to the work carried out by Prof. Benedetto Barberi, General Manager of ISTAT. A group formed by researchers, scientific research bodies, and big Italian enterprises accepted Prof. Barberi's invitation to participate in the formation of AIRO. These people include, but are not limited to, Cav. Lav. (Knight of Labour) Carlo Faina (President of Montedison), Giuseppe Pero (President of Olivetti), Prof. Giovanni Polvani (President of CNR—The National Research Council), Prof. Giuseppe Pompilj (Director of the Probability Calculation Institute in Rome University), Prof. Vittorio Valletta (President of FIAT), and the member of Parliament Prof. Enrico Mattei (President of ENI). Prof. Enrico Mattei (President of ENI), an important person in the Italian industrial history, is amongst the most ardent supporters of the importance of the operations research methods in economic and financial organizations.

In the same year, Prof. Barberi announced the first Work Days (Annual meeting of the

Association), which has become the primary meeting in Italy that deals with operations research from both the methodological and application perspectives. From 1961 to 1968, "Quaderni R.O." was published: the purpose of this seven-issue series was to collect the annual contributions of the Work Days carried out in those years; each of these issues focused on a different theme.

At the beginning of the second half of the twentieth century, industrialized nations faced major problems linked to economic planning, increases in per capita income, and reductions in regional and social economic gaps. This was brought to the attention of operations researchers and ORSA (Operations Research Society of America) in the early 1960s, and was dealt with again on the occasion of the second Conference of IFORS (International Federation of Operational Research Societies). Consequently, the identification of the operations research as an urgent economic planning instrument was introduced to the scientific and productive world through the statement submitted by a group of researchers inside the United Nations at the beginning of 1961. The interest of the United Nations dates back to a vote given by the Economic and Social Board of that organization for a systematic commitment to make the most modern and verified instruments available for the newly developing countries to accelerate their economic development. With regards to Italy, it was Prof. Barberi's desire that operations research, through AIRO, would play an important role in the construction and implementation of the Italian economic development program.

Since the beginning, AIRO has been organized in local chapters that have depended each year upon the assembly regarding the activities carried out that year. The first chapters were established in Turin, Genoa, Milan, Padua, Rome, and Naples.

AIRO publishes an information bulletin that provides information about scientific operations research activities both

at the national and international level. Furthermore, it publishes a series of volumes that explain OR concepts and methods.

In 1970, Prof. Barberi left his office as AIRO President, and, at the members' meeting, Eng. Armando Corso was elected as his successor.

In addition to the activities of the local chapters, new initiatives are carried out, including (but not limited to) the workgroups "Applications of Operations Research to the control of the environment," "Teaching Operations Research in Italy," and "Operations Research in banks."

The information bulletin is accompanied by the publication of the journal "Ricerca Operativa" (Operations Research), published through the support of the National Research Council, which features articles and reviews of scientific books.

In the beginning of the 1970s, there was a considerable increase in interest toward OR by Italian universities. In these years, the first university chairs of operations research were established, and many university courses were started in this discipline.

After two consecutive terms of office, Eng. Corso left the AIRO presidency, and, in 1975, Eng. Bruno Martinoli was elected in his place. AIRO began its cooperation with IFORS and EURO (The Association of European Operational Research Societies) at that time; seven European associations, including AIRO, cooperated in the management of EURO at that time.

At the same time, EURO began publishing the "European Journal of Operational Research," which AIRO has actively supported through qualified cooperation, special issues, and participations in workgroups.

Moreover, at the same time, AIRO began working cooperatively with other Italian scientific communities such as AICA, AISL, ANIPLA, SIRI, and ACM Charter. These activities included the unitary meeting held on March 1977 about "Informatics distributed in the industrial production." OR theoretical bases in those years ranged from matrix and linear algebra to probability, statistics, stochastic processes, calculating machines science, microeconomics, business administration, organization theories, and

behaviour sciences. In particular, it developed mathematics models and methods for linear programming, dynamical programming, queueing theory, network theory, game theory, and simulation.

During the years in which Eng. Martinoli was the President, AIRO cooperated with the organization as a member of EURO and IFORS in many international meetings. These meetings included EURO, Stockholm, 1976; IFORS, Toronto, 1978; EURO, Amsterdam, 1979; EURO, Cambridge, 1980; IFORS, Hamburg, 1981; and EURO, Lausanne, 1982.

With regards to cooperation with similar Italian scientific organizations in order to exchange information, share experiences, and promote common activities, AIRO established a committee composed of the presidents of the following associations: AICA, AIRO, AIS, ANIPLA, and SIRI.

At the beginning of the 1980s, there was a very low presence of corporate applications, as well as an absence of submissions to the annual AIRO conferences from industries where OR had its main development. Conversely, there were many submissions from university and research bodies. This dual-speed development situation of operations research in universities and the private industry continued throughout the 1980s. This brought considerable growth at the university level, but also led to a progressive decrease in OR corporate groups.

In September 1982, the members elected Prof. Massimo Merlino as AIRO President. Prof. Merlino gave the Presidency a more managerial orientation, and 20 important Italian companies joined AIRO. The president established a permanent advisory committee for corporate members, in which any company could participate through a representative. This committee was created to direct the AIRO policy toward the private industry. In particular, many Italian corporations reorientated themselves toward a higher quantitative culture, and they made a higher investment in the local AIRO chapters and the training of young graduates.

During this time period, there were many influential AIRO seminars on various managerial topics such as distribution problems, organizational issues linked to industrial

automation, interactive decision support methods, and combinatorial optimization.

In 1984, the National Operations Research Annual Prize for the best publishing in operations research was established and was given to Italy during the same year.

Corporate membership in AIRO increased by 30%. Research institutions, already strong, continued to grow. AIRO multiplied its central and local activities and improved their quality, enabling the organization to reacquire a prestigious position among Italy's large enterprises and institutions (similar to the position it held in the 1960s). In this period, the President appointed three illustrious honorary members: Senator Prof. Siro Lombardini, Prof. Antonio Ruberti, and Prof. Mario Volpato. The following year Prof. Giuseppe Brambilla was also appointed as an honorary member of AIRO.

Italian companies began looking for more operations research training courses; these organizations showed particular interest in introductory courses on decision techniques. The main methods of corporate interest were production planning, simulation of automation line, decision support systems, expert systems for planning and management of production lines, optimization techniques, and statistics and simulation applied to the factory.

The main element that now distinguished AIRO from other similar associations was the simultaneous presence of university researchers and professionals employed by the private industry and government.

Prof. Merlino eventually left the presidency after two consecutive trienniums recommending the creation of new openings and opportunities for exchange of ideas and information with other disciplines and cultures.

In October 1988, the members elected Prof. Paolo Toth as AIRO President. As a world-famous researcher, he was highly esteemed and appreciated by all those who dealt with OR both in Italy and abroad. In 1998, he was awarded the EURO Gold Medal for scientific merits. He held the office as EURO President from 1995 to 1996 and IFORS President from 2001 to 2003.

Pursuant to a request submitted by AIRO member companies for training courses that addressed institutional deficiencies in the most advanced operations research techniques, AIRO and the Institute for Systems Analysis and Computer Science (IASI) of the National Research Council began to carry out a programme to regulate Operations Research Courses. The courses were extremely popular and became a strength of the association. They were extremely successful due to the high educational level provided by qualified instructors and the presentation of optimization software packages.

AIRO simultaneously implemented a policy to increase exposure to operations research among young people (university and high school students) to create interest and participation in the subjects of our discipline. The actions that were carried out ranged from the identification of the topics that must be dealt with by OR to the choice of pilot schools for experimentation. The experimentation was supported by the Ministry of Public Education and had the training of teachers and subsequently students as its objective, providing them with the methodological tools that would enable them to deal with various kinds of decisional problems that young people have to face in their future work activities.

In order to promote the connection between scientific research and industrial applications, AIRO and Ferrovie dello Stato (Italian State Railway Institution) announced two International contests (F.A.R.O. and F.A.S.T.E.R.). These contests were intended specifically to promote the development of large-scale resource optimization methods applied to train management and personnel rostering.

In September 1995, Prof. Toth left the presidency and the members elected Prof. Giorgio Gallo as AIRO President. Training activities continued intensively through company-oriented courses. In this period, companies faced continuous change in the market, fast technological development, and the necessity of adjustment to the production processes. The significance of operations

research was increased through the improvement in computer science technologies that offered increasingly effective contributions to the solution of the abovementioned issues.

After recognizing the opportunity for a better integration with similar European associations, the President suggested the publication of a journal by AIRO and the Belgian and French associations. In 2001, the journal "Ricerca Operativa" ended its publishing with the issue of no.100, and the international journal "4OR" was published by Springer. This journal promptly acquired a high scientific level. Prof. Silvano Martello represented AIRO as one of the founding editors-in-chief of this new journal.

In those years, AIRO began publishing a news bulletin named "AIRONews" in both print and on the Internet. It was received very favourably by members and followers.

Pursuant to the proposal of the AIRO Steering Committee, the members' meeting appointed Prof. Lucio Bianco and Prof. Sergio De Julio as honorary members.

In September 2001, the members elected Prof. Roberto Tadei as the AIRO President.

He set the following goals for AIRO:

- analysis of corporate training needs;
- offering short courses, both inter-corporate and corporate, in the following fields: assessment of the marketing operations, logistics instruments, instruments for simulation and optimization, and methodologies and techniques for project financing and project management;
- publication, both print and on the Internet, of a monthly information brochure for the enterprises that illustrate successful applications of the operations research within the companies;
- setting up "Windows about Operations Research," a presentation by research groups in Italian universities of the products that they have developed for the private industry;
- realization of a service to facilitate the joint participation of companies and research centres in the European and National research projects.
- The reinforcement of the connection with young people through the extension of graduation awards (both for high schools and master's degree) as well as the establishment of a contest for high school students to increase the involvement of younger students and their teachers in our discipline.
- The creation of on-line databases that could collect employment applications and offers, making graduates aware of companies looking for individuals trained in operations research and of available training programs in operations research.
- The creation of a Thematic Chapter "AIRO Giovani" (AIRO Youth) to (i) support a network of relationships and competencies among young people and (ii) propose training for PhD courses and initiatives that aim at specialization and extension of research competencies in young people.

Furthermore, alongside the journal "4OR," the news bulletin AIRONews enforces the objective of spreading OR in Italy. There are two main branches, the first oriented to industry and the second oriented to education (universities and schools). The most qualifying proposals consist of submitting not only technical articles but also informative ones, publishing thoughts about daily life, taking care of the diffusion of the news bulletin so that specific people in companies and bodies are reached. This also enables cooperation with similar journals of other associations.

In addition, the internet publication ImpresAIRO is initiated; this is a readable journal intended for companies and is an instrument through which companies communicate with each other to show the relevant benefits of applying operations research methods to production processes.

Raising awareness and appreciation of OR among young people was one of the most important objectives of AIRO in those years. Indeed, initiatives were developed for the following:

In 2003, another new initiative was carried out. This initiative established an annual meeting, called *AIROWinter*, to be held during the winter in a mountainous location (the first event took place in Champoluc, Aosta Valley, Italy). The objective of these meetings was to gather Italian and foreign research groups working in the fields that were important to Prof. Mario Lucertini (a famous OR researcher who died prematurely in 2002 and to whom this meeting was dedicated). The meeting was organized in the following year to also remember Stefano Pallottino, another illustrious colleague who died prematurely in 2004.

On the occasion of the “Work Days” in 2005, as acknowledgment of the noteworthiness support given to the association when they were holding the office of president, the following past presidents were named as AIRO honorary members: Prof. Armando Corso, Eng. Bruno Martinoli, Prof. Massimo Merlini, Prof. Paolo Toth, and Prof. Giorgio Gallo.

On the occasion of the “Work Days” in 2006, pursuant to the proposal of a jury composed of the three editors-in-chief of the journal “4OR,” there was the appointment of the first AIRO fellow members: Prof. Giorgio Gallo, Prof. Pierre Hansen, and Prof. Paolo Toth.

Other Italian scientific associations (in particular AMASES and SIMAI) have been contacted in order to establish a common cooperation and to promote the realization of the Federazione Italiana di Matematica Applicata (FIMA), which is the Italian Federation of Applied Mathematics. FIMA has two purposes. First, on a national level, FIMA organizes common meetings, provides integrated training courses, and coordinates the activities of individual associations. Second, on an international level, FIMA

aims to engage with similar federations and associations of other European countries. Indeed, in addition to the research projects, in which it is hard to participate in the framework of scientific associations, there are many other projects aimed at propagating the results and training young people and companies. The structure and the organization of such associations can play an important role.

As its first initiative, in January 2006, FIMA organized the First International Conference FIMA with the theme “Models and Methods for Human Genomics,” in Champoluc (in the Aosta Valley of Italy) to encourage greater Italian and foreign participation in this area. On the basis of the works presented during the meeting, FIMA published a special issue of the journal *Computers and Mathematics with Applications*, entitled “Modelling and Computational Methods in Genomics.”

In September 2006, Prof. Renato De Leone was elected as AIRO President, and he still holds this office. This President has launched many interesting initiatives in Italy and abroad that promise to play very important roles in the future of the Italian Association of Operations Research.

Acknowledgments

The paper is based on “Storia dell’Associazione Italiana di Ricerca Operativa”, by Agnese Martinoli in *Scienza delle decisioni in Italia: applicazioni della Ricerca Operativa a problemi aziendali*, ECIG 2008, pp. 21–32. Mrs. Martinoli, now retired, has held her office as AIRO Secretary for almost 40 years, proving to be an indispensable reference for the Association, its presidents, and to all of the members. We would like to express our most sincere thanks to Mrs. Martinoli.

OPTIMIZATION FOR DISPATCH AND SHORT-TERM GENERATION IN WHOLESALE ELECTRICITY MARKETS

GOLBON ZAKERI

Electric Power Optimization Center,
Department of Engineering Science,
Faculty of Engineering, University of
Auckland, Auckland, New Zealand

INTRODUCTION

The first example of energy market concepts and privatization of electric power systems took place in Chile in the early 1980s. The idea behind the Chilean model was to bring rationality and transparency to the operations of the power system that would ultimately be reflected in power prices. Other rationales for the eventuation of electricity markets include better reliability (e.g., in the case of Argentinean electricity market) and signaling appropriate levels of investment in infrastructure in the energy sector. Today many countries and jurisdictions rely on electricity markets to meet their electricity needs. These include UK, Australia, New Zealand, the Nordpool market consisting of Scandinavian countries, Brazil and other South American countries, as well as many jurisdictions in the US.

Electricity markets typically consist of five main sectors: the system operator (sometimes there is also a separate transmission system operator), generators, consumers, distributors, and regulatory bodies overseeing the regulations and operations of the market. While operations research is utilized in each one of these sectors on a day to day basis, to keep this article to a reasonable length and be informative, we only discuss the first two sectors. In what follows, we describe the operation of an electricity market. We then discuss the generation sector and describe how operations research is utilized within that sector.

MARKET OPERATION AND THE SYSTEM OPERATOR

Electricity is not a storable commodity. It is injected into a transmission grid at certain nodes of that transmission grid often referred to as grid injection points (GIPs), and flows through the grid complying with physical constraints. Electricity is withdrawn at grid exit points (GXPs) and delivered to consumers. Owing to the physical constraints on the flow of electricity, in all electricity markets, the dispatch of electricity generation is left to an independent system operator (ISO). In most electricity markets, an additional function of the ISO is to determine the price of electricity at different nodes of the transmission network.

Economic Dispatch

Typically, in a wholesale electricity market, in each period of the day, each generator offers in generation quantities for each of its plants (possibly located at different GIPs), at certain prices. In its most general form, the generation offers are supply functions (also known as offer curves) denoted as $p = C(q)$, where $C(q)$ is the marginal price of producing quantity q . These supply offers are collected by the ISO. The ISO also estimates the demand over that period. The ISO then solves the so-called economic dispatch problem (EDP) which is also known as the optimal power flow problem. This is the optimization problem outlined in EDP below. For the readers familiar with optimization, EDP is a side-constrained network optimization problem where the objective is to minimize the total cost of production of electricity. The constraints of this optimization problem reflect that demand must be met at every node of the network, and that physical constraints such as transmission line capacities and Kirchhoff's laws govern the actual flows. Typically, system operators solve such an optimization problem on at least an hourly basis. Often reactive power modeling is left out of the

ISO's dispatch problem and the problem is in fact a direct current equivalent load flow model [1,2]. A general model for the ISO's EDP is formulated below.

$$\begin{aligned}
\text{EDP: } & \text{minimize } \sum_i \sum_{m \in \mathcal{O}(i)} \int_0^{q_m} C_m(x) dx \\
& \text{s.t. } g_i(y) + \sum_{m \in \mathcal{O}(i)} q_m \\
& \quad = D_i, \quad i \in \mathcal{N}, \quad [\pi_i] \\
& \quad q_m \in Q_m, \quad m \in \mathcal{O}(i), \\
& \quad i \in \mathcal{N}, \\
& \quad y \in Y.
\end{aligned}$$

We use i as the index for the nodes in the transmission grid. We use m as the index for the generators, and $\mathcal{O}(i)$ indicates the set of all generators located at node i . Generator m submits marginal cost curve C_m to the ISO and is called upon to supply quantity q_m . The demand at node i is denoted by D_i . Q_m indicates the capacity of generator m .

Here the components of vector x measure the dispatch of each generator and the components of the vector y measure the flow of power in each transmission line. We denote the flow in the directed line from i to k by y_{ik} , where by convention we assume that $i < k$. (A negative value of y_{ik} denotes flow in the direction from k to i .) It is required that the vector of line flows lies in the convex set Y , which means that each component satisfies the thermal limits on each line, and satisfies loop flow constraints that are implied by Kirchhoff's Law. The function $g_i(y)$ defines the amount of power arriving at node i for a given choice of y . This notation enables different loss functions to be modeled. For example, if there are no line losses, then we obtain

$$g_i(y) = \sum_{k < i} y_{ki} - \sum_{k > i} y_{ik}.$$

With quadratic losses (where r_{ik} denote the appropriate loss coefficient for the quadratic

loss), we obtain

$$\begin{aligned}
g_i(y) = & \sum_{k < i} y_{ki} - \sum_{k > i} y_{ik} - \sum_{k < i} \frac{1}{2} r_{ki} y_{ki}^2 \\
& - \sum_{k > i} \frac{1}{2} r_{ik} y_{ik}^2.
\end{aligned}$$

As indicated above, one of the functions of the ISO is to set the price. The price of electricity is determined as the shadow price π_i of the node balance constraints above, which indicates that demand must be met at all nodes. This price is the system cost of meeting one more unit of demand at node i . This method of determining the electricity price is sometimes referred to as locational marginal pricing (LMP). New Zealand and the PJM market in the US are examples of electricity markets with LMP.

It is worth noting that some wholesale electricity markets operate by assuming that demand and supply are located at the same node and trading takes place in that one node. This means that a single price of electricity is found. Nevertheless, in order to ensure that the demand is met at all nodes and that the flow complies with physical constraints, a balancing market would follow in real time where the residuals of the single node market are traded. The UK wholesale electricity market is an example of a single node market.

Unit Commitment

While the EDP described so far minimizes the total cost of generation based on the generators' offers, it is concerned with cost minimization over a single period. Besides the marginal cost of running generation units, other costs such as start up and shut down costs and constraints such as minimum up and down time for the generation units may need to be considered. In some markets, these concerns are left to the generators. They are to figure these costs and constraints and reflect them in the way they offer their generation into the market. Other markets, such as the PJM, have unit commitment constraints embedded, and the EDP runs over a time horizon spanning a day. For a comprehensive discussion on the unit commitment problem

and the problem of market design embedding unit commitment see Ref. 3.

GENERATORS

The generation sector in wholesale electricity markets usually consists of coal or gas fired thermal, nuclear power, hydro-electric, and/or other renewable (such as wind or solar powered) generation. As mentioned above, generators in a wholesale electricity market are required to submit an offer curve for each of their generation units. Therefore, the main question faced by any generator in a wholesale electricity market is how to offer into the market in such a way as to maximize its return. Before we explore this problem further we must make a distinction between two different types of generators, the so-called price makers and price takers. We should also note that since the future is uncertain and neither the competitor offers nor the demand is known, assuming risk neutrality, the generators will be maximizing their expected profits.

Price-Taker Generators

A generator is defined to be a price taker if the (nodal) price of power is not affected by the generation strategy of the generator. A true price taker is likely to have a small capacity for generation (relative to the rest of the market) with correspondingly little storage capacity. Therefore, the typical time horizon for the optimization problem is short to medium term. Here, the only significant uncertainty is in the electricity price process. Other factors such as inflows (in the case of a hydro generator) and the price of thermal fuel (in the case of coal or gas generators,) may be treated as deterministic as they are well forecasted over the short time horizon. If the electricity prices were independent from period to period, then the optimal policy would be to submit a generation offer so that dispatch is ensured if the electricity price is above expectation and no generation is dispatched (therefore, resources such as water are saved for the subsequent period) if the price is below expectation. However, this

independence assumption does not hold for electricity prices.

Pritchard and Zakeri [4] focus on a price-taker hydro generator operating a river chain. They have developed a time inhomogeneous Markov model for electricity prices (at a node); here the transition probabilities depend on the time of day and the time of week. They use this price process to set up and solve a stochastic dynamic program in order to determine the release policies for operating a river chain, so that the expected profit of a price-taker hydro-electric generator is maximized.

In a subsequent paper, Pritchard *et al.* [5] relax the assumption of limited storage. Here, they consider a model where weekly expected releases for a river chain are determined on the basis of a long-term model for electricity prices. This expected release, along with a standard deviation on release, is then passed to another optimization problem with a much shorter time horizon that focuses on a particular week. They then construct period to period offer stacks for the week in question using dynamic programming. This model integrates the long- and short-term plans and allows for target release levels (the expected release each week) as well as allowing deviations from this target should an opportunity present itself in the shorter time horizon model to take advantage of favorable prices.

Conejo *et al.* [6] develop a model that addresses similar questions pertaining to a thermal generator. The maximum output of a thermal unit is not available instantaneously. Thermal generators are bound by their ramp rate characteristics that dictate how the generator's available output rises toward its maximum output as a function of time. They must also comply with minimum up and down constraints that constitute them; once a unit is turned off it may not be turned on again until some time has elapsed and vice versa. Conejo *et al.* develop a mixed integer linear program that produces a bidding strategy for a price-taker thermal generator over the course of a day given a price forecast for electricity prices that day. This bidding strategy maximizes the generator's expected profit. It should be noted that

while most models in the literature assume that the generators are risk neutral and aim to maximize expected profits, there has been some research addressing production schedules in the presence of a risk attitude; see, for example, Ref. 7. For further reading on price-taker generation optimization see also Refs 8–10.

Price-Maker Generators

Owing to economies of scale and the spatial distribution of consumers, almost all electricity markets are oligopolies. Therefore, the most natural setting for a model is to assume that the offer strategies of a generator influence the (nodal) price of electricity. In such a setting, the generators' fundamental profit maximization question needs to be revisited. The price of electricity is no longer exogenous; hence, the profit optimization problem faced by the generator now must take into account how the actions of the generator influence the price of electricity. This problem was first addressed in a paper by Klemperer and Meyer [11], who were interested in modeling an oligopoly facing uncertain demand, where each firm bids a supply function as its strategy. This is in contrast to previous models in the economics literature where firms were restricted to strategize over their quantities only (Cournot models) or their prices only (Bertrand models) and allows a firm to adapt better to an uncertain environment. Green and Newbery address the same question but in the context of the British spot market [12].

To begin, let us assume that there are only two generators supplying the market (i.e., we are dealing with a duopoly) and suppose that the offer curve of the competitor is given by $q = S(p)$. Let us also assume that the demand curve is given by $q = D(p)$, that is, the market will absorb quantity q if the price is p . For their analysis, Klemperer and Meyer use the concept of the residual demand curve faced by the generator. Consider the curve given by $q = D(p) - S(p)$. This determines what quantity must be offered into the market if we desire the price to be p based on the demand curve and the competitor's offer strategy. The inverse of this curve describes how the price is influenced by the quantity we offer and is referred to as the residual demand curve. Therefore, for any potential offer quantity q , we can obtain the corresponding market clearing price p from the residual demand curve, and the product $q \cdot p$ will yield the revenue associated with that (potentially) offered quantity. With this information at hand, it is now easy to optimize our profits (see Fig. 1); we simply choose to offer in the quantity q that will maximize revenue less cost of production.

Recall that Klemperer and Meyer point out that supply functions allow a firm to adapt better to an uncertain environment. If there are multiple possible residual demand curves that a generator may face, the supply function response may allow selection of a point on each of these residual demand curves that would optimize the generator's profit given that residual demand curve

Figure 1. Optimal point for a generator to get dispatched along a residual demand curve.

Figure 2. Building a strong supply function response from a distribution of residual demand curves.

has realized. This is referred to as a strong supply function response (see Fig. 2). A number of papers construct the residual demand curve by simulating the (single node) market and explicitly building the supply function response, see, for example, Refs 13 and 14. In Ref. 13, the residual demand curve takes on a step function form and the authors develop a nonlinear integer programming model of the generator's revenue optimization problem. They develop a combined coordinate search, branch and bound method, to solve this problem. Torre *et al.* exploit the nature of the previous problem to develop a more efficient solution method [14]. Baillo *et al.* further consider a robust price-maker decision problem that is an extension to the previous work [15].

In a sequence of papers Anderson and Philpott have also addressed the profit maximization problem of a price-maker generator under various assumptions. In Ref. 16, they assume that a price-maker generator knows its competitors' offer curves, but is faced with uncertain demand. They first establish the existence of a strong supply function response, for such a generator, that would be optimal for any realization of the uncertain demand. This strong supply function response is guaranteed to exist when the generation costs of the generator in question are increasing and convex, and the competitor offers are log concave. They discuss a procedure where the true aggregate offer stack of the competitors is approximated by a log concave function. Note that this (aggregate)

offer stack would be a step function in almost all real-world electricity markets. They construct a strong supply function response, S_g , for the generator in question. Subsequently, they approximate S_g in order to comply with market rules. Finally, they provide bounds on the performance of such an offer strategy.

In Ref. 17, Anderson and Philpott generalize their model by allowing uncertainty not only in the demand but also in the competitor offers. They introduce the concept of a market distribution function $\psi(q, p)$ pertaining to a specific generator at a specific transmission node. They define $\psi(q, p)$ to be the probability of not being fully dispatched if the generator submits a quantity q at price p . Let $R(q, p)$ denote the profit that the generator makes if it is dispatched quantity q at a clearing price of p . They demonstrate that if the generator submits the curve s and the pertinent market distribution function ψ is continuous, then the expected profit of the company is given by

$$V(s) = \int_s R(q, p) d\psi(q, p).$$

They proceed to provide conditions that guarantee (local) optimality of an offer stack s that would maximize $V(s)$. To address the question of estimating the market distribution function see Refs 18 and 19.

The work described thus far only deals with generators that are located at a single node of the market or alternatively assumes

that the wholesale market is a single node market. As noted in the section titled “Market Operation and the System Operator,” however, most wholesale electricity markets use locational marginal pricing where the price of electricity is different from node to node. To capture the effects of the transmission network, a generator must look at the variations in the prices from the dispatch problem EDP as a function of how it offers into the market. The revenue optimization problem is now posed as a bilevel program, or a mathematical program with equilibrium constraints (MPEC) and becomes a nonconvex optimization problem.

$$\begin{aligned}
 & \text{maximize } R(x, \pi) \\
 & \text{s.t. } (x, \pi) \in \arg \min \sum_i \sum_{m \in \mathcal{O}(i)} \int_0^{q_m} C_m(x) dx \\
 & \text{s.t. } g_i(y) + \sum_{m \in \mathcal{O}(i)} q_m = D_i, \quad i \in \mathcal{N}, \\
 & \quad q_m \in Q_m, \quad m \in \mathcal{O}(i), \quad i \in \mathcal{N}, \\
 & \quad y \in Y.
 \end{aligned}$$

Here x denotes the vector of quantities dispatched at each node if the generator offered at that node (or is 0 if the generator in question does not own generation at a particular node), and π is the vector of electricity prices. Note that the inner optimization problem, namely, the economic dispatch problem EDP can be replaced with its necessary and sufficient conditions for optimality as it is a convex problem (see, e.g., chapter 4 of [20]). In this case, the reformulation is referred to as an MPEC [21]. Several papers have addressed this problem and have developed techniques to produce local or global optimal solutions for it (see, e.g., Ref. 22). In Ref. 23, Fampa *et al.* develop a stochastic version of the above problem in which they consider various demand and market clearing scenarios. This results in a number of follow-on economic dispatch problems. They propose some heuristic methods for solving this problem. Pritchard also considers a stochastic version of the above problem [24]. In his model, the generator in question only owns generation assets at a single node of the transmission

network. He proposes a stochastic dynamic program to solve the generator optimization problem. It should be noted that the literature surveyed for price-maker generators is only concerned with short- to medium-term time horizons, where a reasonable distribution for competitor behavior and demand, or a reasonable estimate of the market distribution function, is available to a generator.

OTHER ELECTRICITY SECTORS

The focus of this short article has been on the generation side of wholesale electricity markets. Operations research is utilized in every sector of the electricity market, and in this section we provide a very brief overview of how it is utilized by the demand side and the regulators.

Consumers of electricity can be loosely classified as major or minor users. Major users of electricity are typically large industrial users who have the ability to observe electricity prices in real time. In many wholesale electricity markets, such users can also bid into the electricity market by specifying a demand curve where they indicate their willingness to consume at different prices. These consumers are similar to price-maker generators in that they have the ability to alter the price of electricity (through the amount that they consume). Frequently, they are not only able to withdraw electricity from a GXP but they may also be in a position to produce their own power through a gas or diesel generator say, or they may have flexibility to reduce their production of goods, which translates into reduction in consumption of electricity. Gomez-Villalva and Ramos [25] have developed a mixed integer linear program for such an industrial consumer in a wholesale electricity market.

For some major consumers, it may also be possible to shift the electricity usage from one period to another, albeit at a cost. Large industrial chillers may be able to cool their contents at earlier hours of the morning to lower degrees simply because the price of electricity is lower in those off-peak periods. The cooler may be able to retain the

low temperatures reasonably well and hence reduce its electricity consumption in the peak morning hours thereby reducing its total cost of consumption. This is referred to as load shifting. Middelberg *et al.* [26] study an optimal control model for load shifting with application to energy management of a colliery.

Regulators are interested in designing electricity markets so that they are as competitive as possible and an efficient and reliable supply is accomplished. They are also interested in diagnosing any ill functioning, such as abuse of power by generating firms, and introducing regulation that would prevent such behavior. They are therefore interested in models of steady-state behavior of the market. There is a vast amount of literature on such models ranging from models that derive Nash–Cournot equilibria and supply function equilibria to agent-based simulation models. For additional information, see Refs 11, 27–36.

OPTIMIZATION MODELS FOR CANCER TREATMENT PLANNING

WENHUA CAO
GINO J. LIM
Department of Industrial
Engineering, University
of Houston, Houston,
Texas

INTRODUCTION

The National Cancer Institute estimates that 1,479,350 new cancer cases are expected to be diagnosed in the United States in 2009 [1]. They also estimate that about 562,340 Americans are expected to die of cancer this year. Cancer is the second leading cause of death in the United States, exceeded only by heart disease. Types of cancer treatment are determined by the cancer site and staging. Most common cancer treatments are surgery, radiation therapy, and chemotherapy. Other types include immunotherapy, targeted therapy, and photodynamic therapy. Physicians often use a combination of these treatments to obtain the best results.

The ultimate goal of various cancer treatments is to kill all cancerous cells without damaging patient's normal tissue and function. However, due to the proximity of healthy organs to the tumor volume, it is almost impossible to completely spare healthy tissues during the treatments. As the oldest form of cancer treatment, surgery is often used to remove localized cancerous cells; that is, it can be an option for those patients whose tumor has not spread out to other areas of the body. Surgeries still face risks and side effects. Radiation therapy uses different types of radiation particles such as photons, electrons, and protons to sterilize the tumor or stop cancerous cells from proliferation. There are two kinds of radiation therapy: the external (beam) radiation therapy or teletherapy uses external

radiation beams for treatment, and the internal radiation therapy or brachytherapy places radioactive sources inside or close to the tumor. Both types of the radiation therapy methods have been increasingly utilized for treating many cancers such as brain, lung, breast, bladder, and prostate, to name a few. Effective plans of radiation treatments require delivery of high dose of radiation to the tumor region while minimizing dose on the normal cells as much as possible. On the other hand, chemotherapy or a drug therapy uses medicines (drugs) to eliminate cancer. Patients can take medicines alone or combine with other treatments.

Designing a cancer treatment plan often involves a series of optimization problems with different kinds of objectives and constraints. Researchers in the optimization community have made significant contributions in improving the quality of various treatment plans for cancer patients: surgery [2], radiation therapy [3–6], and chemotherapy [7,8].

This article presents planning problems of major cancer treatments, and mathematical and computational optimization models that have been developed to solve them. The rest of the article is organized as follows. The second section introduces external radiation therapy planning problems including gamma knife, conventional three-dimensional conformal radiation therapy (3DCRT), intensity modulated radiation therapy (IMRT), and proton therapy, and a few optimization methods that are developed specifically for such treatment modalities. The third and fourth sections discuss cancer treatment models for brachytherapy and chemotherapy. And, the final section summarizes the article with future research directions.

EXTERNAL RADIATION THERAPY

Treatment Delivery and Optimization

In external radiation therapy, radiation is delivered from outside the body and

directed at the patient's tumor location using special radiation delivery machines. Different devices produce different types of radiation and they include Cobalt-60 machines for gamma knife radiosurgery, linear accelerators for IMRT, neutron beam machines, orthovoltage X-ray machines, and proton beam machines. With the exception of the gamma knife radiosurgery, most treatments are administered over several weeks. Patients receive small dose of radiation each day until the total prescribed dose is delivered. Such a regimen is used to protect normal tissues from being damaged by radiation, since they can have time to recover. If the treatment volume is sufficiently irradiated, the tumor may well be eliminated. But, a significant amount of normal tissues would also be damaged. This is not a desirable outcome of a treatment.

Before a radiation therapy treatment planning takes place, physicians need to obtain precise geometric information of the tumor from a patient. Several scanning procedures, such as computed tomography (CT), magnetic resonance imaging (MRI), or positron emission tomography (PET), are mainly used. These diagnostic images then help physicians determine the three-dimensional shape, location and size of the tumor, and surrounding normal tissues. Conventionally, there are three types of volumes to be considered: *planning target volume* (PTV), *organs-at-risk* (OARs) or *critical structures*, and normal tissues. PTV includes the suspected cancerous area; OARs are organs located close to the PTV where receiving some minor radiation dose is acceptable; and all remaining portions are normal tissues. The physician designs the *prescription* for radiation treatment that delivers a sufficient amount of radiation dose on the PTV to kill cancer cells while limiting radiation on the OARs and the normal tissues. These are two conflicting objectives in radiation treatment planning. One may easily expect a trade-off between these two objectives. Thereby, upper and lower bounds of radiation doses are employed to guarantee a successful treatment plan according to radiation treatment planners' experiences. Optimization methods are often used to find

a clinically acceptable solution that is a compromise between the two objectives [9].

The quality of a treatment plan can be measured by *uniformity*, *conformity*, and *avoidance* [5]. It is important for a treatment plan to have uniform dose distributions on the target, so that *cold* and *hot spots* can be minimized. A *cold spot* is a portion of an organ that receives less than its required radiation dose level. On the other hand, a *hot spot* is a portion of an organ that receives more than the desired dose level. The uniformity requirement ensures that radiation delivered to the tumor volume will have a minimum number of *hot spots* and *cold spots* on the target. This requirement can be enforced using lower and upper bounds on the dose, or approximated using penalization. The conformity requirement is used to achieve the target dose control while minimizing the damage to OARs or healthy normal tissue. This is generally expressed as a ratio of cumulative dose on the target over total dose prescribed for the entire treatment. This ratio can be used to control conformity in optimization models. As we mentioned earlier, a great difficulty of producing radiation treatment plans is the proximity of the target to the OARs. An avoidance requirement can be used to limit the dose delivered to OARs. Finally, simplicity requirements state that a treatment plan should be as simple as possible. Simple treatment plans typically reduce the treatment time as well as implementation error. These above-mentioned requirements provide guidelines for most treatment planning optimization models.

In the rest of this section, we discuss some optimization models and techniques that are practically useful for radiation treatment modalities: gamma knife radiosurgery, 3DCRT, IMRT, and proton therapy.

Gamma Knife Radiosurgery

Background. The gamma knife is an important device for treating tumors or vascular malformations located in patient's head [10]. It can deliver a single beam of high dose of radiation by 201 Cobalt-60 unit sources. All 201 beams simultaneously intersect at the same location to form an

approximately spherical region that is typically termed as *shot of radiation*. Multiple shots are often used in a treatment using a gamma knife due to the irregularity and size of tumor shapes and the fact that the focusing helmets are available only in four sizes (4, 8, 14, and 18 mm). The objective of treatment planning is to deliver a high dose of radiation to the intracranial target volume with minimum damage to the surrounding normal tissue. The uniformity, conformity, and avoidance are necessary requirements to a treatment plan. Treatment optimization models are constructed to incorporate these requirements, which may be case specific of different doctors and patients. In addition, minimization of the number of shots is also preferred.

Optimization Models. The optimization problem of the gamma knife radiosurgery treatment planning aims to determine the locations and duration times for different shots. Corresponding integer variables are usually included in the optimization model. A mixed integer nonlinear programming (MINLP) has been introduced by Ferris *et al.* [3].

Suppose that the number of radiation shots for the treatment is given *a priori*. Adding the goal of minimizing this number to the optimization model is typically straightforward. However, solving such models can be extremely difficult.

Decision Variables. Let T denote the subset of tumor voxels and N denote the subset of voxels that are not in the tumor. Let $D_{i,j,k}$ denote the amount of radiation dose that a voxel (i,j,k) receives. In general, there are three types of decision variables:

1. a set of shot center locations (x_s, y_s, z_s) for $s \in S$;
2. a discrete set of collimator sizes w ($w \in W$);
3. radiation exposure time $t_{s,w}$ for each radiation shot.

It is assumed that the dose contribution $d_w(x_s, y_s, z_s, i, j, k)$ to voxel (i, j, k) from a shot centered at (x_s, y_s, z_s) with width w is given

in the model. Thus, the total dose delivered to the voxel (i, j, k) can be calculated by

$$D_{i,j,k} = \sum_{(s,w) \in S \times W} t_{s,w} d_w(x_s, y_s, z_s, i, j, k). \quad (1)$$

Constraints

1. Uniformity—Isodose Line Coverage.

A treatment plan is normally considered acceptable if a $\theta\%$ isodose curve encompasses the tumor region. For example, 50% isodose curve is a curve that encompasses all voxels that receive at least 50% of the maximum radiation dose that is delivered to any voxels in the target volume.

2. Choosing Shot Sizes.

The location of a shot center can be chosen by a continuous optimization process, while the width at each shot location can be determined by a discrete optimization process, for example, binary integer programming. Thus, the number of shots used can be counted by tracking the exposure time $t_{s,w}$; that is, a shot is used when $t_{s,w}$ is positive. Let n denote the total number of shot and width combinations, then it is valid that $n = \sum_{(s,w) \in S \times W} H(t_{s,w})$, where H is the step function.

An optimization model of Ferris *et al.* [3] is described as follows:

$$\begin{aligned} \min \quad & \sum_{(i,j,k) \in N} D_{i,j,k} \\ \text{s.t.} \quad & D_{i,j,k} = \sum_{(s,w) \in S \times W} t_{s,w} d_w(x_s, y_s, z_s, i, j, k) \\ & \theta \leq D_{i,j,k} \leq 1, \quad \forall (i,j,k) \in T \\ & n = \sum_{(s,w) \in S \times W} H(t_{s,w}) \quad t_{s,w} \geq 0. \end{aligned} \quad (2)$$

The most critical problem for solving the optimization model (2) is the large number of voxels that are needed when dealing with large irregular tumors (both within and outside of the target). This makes the optimization problem computationally intractable. One approach to overcome this problem is by removing a large number of the nontarget voxels from the model. Although this improves the computation time, the conformity of the dose to the target is

typically weakened. Ferris *et al.* [3] propose a sequential solution approach to speed up the time while maintaining conformity. First, a *coarse grid* problem is solved as a nonlinear programming (NLP) model using a set of systematically reduced data points. Then the *finer grid* NLP problem with full data points is solved using the starting point that was obtained by the coarse grid model in the previous stage. Typically, the solution from this finer grid model is very close to a good local optimum for the MINLP. Using this solution, the full MINLP model is finally solved to determine the values of the three sets of decision variables for this problem.

Three-Dimensional Conformal Radiation Therapy

Background. 3DCRT is able to utilize 3D imaging data of tumor and surrounding anatomy to achieve high conformal dose of radiation delivered to the target volume, and therefore reduce the dose to normal tissues. This treatment can be administered for a variety of cancers. In 3DCRT, multiple external beams are generated by a linear accelerator and directed from different angles into the target volume (see Fig. 1a). Most importantly, each beam can be shaped by a computer automated multileaf collimator (MLC), which is mounted on a gantry

to confirm the *beam's-eye-view* of the tumor (see Figure 1b). Hence, a three-dimensional geometry can be confirmed by these beams using anatomical information.

Wedge Filters. A wedge (also called a *wedge filter*) is a tapered metallic block with a thick side (the *heel*) and a thin edge (the *toe*) (see fig. 2). This metallic wedge varies the intensity of the radiation in a linear fashion from one side of the radiation field to the other. When the wedge is placed in front of the aperture, less radiation is transmitted through the heel of the wedge than through the toe. 2b shows an external 45° wedge, so named because it produces isodose lines that are oriented at approximately 45° . The quality of the dose distribution can be improved by incorporating a wedge filter into one or more of the treatment beams. Wedge filters are particularly useful in compensating for a curved patient surface, which is common in breast cancer treatments.

Two different wedge systems are used in clinical practice. In the first system, four different wedges with angles 15° , 30° , 45° , and 60° are available, and the therapist is responsible for selecting one of these wedges and inserting it with the correct orientation. In the second system, a single 60° wedge (the *universal wedge*) is permanently located on a motorized mount located within the head

Figure 1. Multiple beams and beam's-eye-view: (a) Multiple external radiation beams. (b) A beam's-eye-view is a 2D shape of a tumor viewed by the beam source at a fixed angle.

Figure 2. Wedges: (a) a wedge filter and (b) an external wedge.

of the treatment unit. This wedge can be rotated to the desired orientation or removed altogether, as required by the treatment plan.

Optimization Models. Suppose that the data to the optimization models is given. Let $d_{(i,j,k),A}$ be the dose contribution to voxel (i,j,k) from a beam of weight 1 from angle A , S be a collection of voxels in the sensitive structure(s), and N be a collection of voxels in the normal tissues. When wedges are allowed in the optimization, the data will be provided as $d_{(i,j,k),A,F}$ that represents the dose contribution to voxel (i,j,k) from a beam of weight 1 from angle A , using wedge orientation F .

Beam Weight Optimization. The classical optimization problem in conformal radiation therapy is to choose the weights (or intensity levels) to be delivered from a given set of angles. Suppose, w_A represents the beam weight assigned to angle A , $D_{(i,j,k)}$ represents the total dose deposited to voxel (i,j,k) , and λ represents the relative weighting factors in the objective function. Given a set $\Omega = \{T \cup S \cup N\}$, a general optimization model that determines optimal radiation intensity is

$$\begin{aligned}
 \min_w \quad & \lambda_t f(D_T) + \lambda_s f(D_S) + \lambda_n f(D_N) \\
 \text{s.t.} \quad & D_{(i,j,k)} = \sum_{A \in \mathcal{A}} d_{(i,j,k),A} w_A, \\
 & \forall (i,j,k) \in \Omega, \\
 & l \leq D_T \leq u, \\
 & 0 \leq w_A, \forall A \in \mathcal{A}.
 \end{aligned} \tag{3}$$

Hard upper and lower bound constraints, that is, u and l , are imposed on the target

dose, so that, in the worst case, the resulting solution will satisfy the minimum requirement for a treatment plan. The penalty function $f(D)$ in the objective function can be defined based on the planner's preference, but a general function can be written as

$$f(D) = \|D(\cdot) - \theta\|_p, \quad p \in \{1, 2, \infty\}.$$

Note that, θ is the desired dose level for an organ of interest. These problems can be cast as a quadratic programming (QP) problem ($p = 2$), minimizing the Euclidean distance between the dose delivered to each voxel and the prescribed dose [11]. Furthermore, linear programming (LP) has also been extensively used to improve conventional treatment planning techniques [12]. The strength of LP is its ability to control *hot* and *cold* spots or integral dose on the organs using constraints, and the presence of many state-of-the-art LP solvers. The LP model replaces the Euclidean norm objective function of a QP with a convex one, for which standard reformulations [5] result in LP problems. While these techniques still suffer from large amounts of data in $d_{(i,j,k),A}$, they are typically solved in acceptable time frames. These models tend to find optimal solutions more quickly than the corresponding QP formulations.

Equivalent Uniform Dose (EUD). Some of the medical physics literature has been advocating the use of other forms of objective function in place of the ones outlined above. A popular alternative is that of generalized equivalent uniform dose (EUD) [13]. This is

defined on a per structure basis as

$$\text{EUD}_a(D, \Omega) := \left(\frac{1}{\text{card}(\Omega)} \sum_{(i,j,k) \in \Omega} D_{(i,j,k)}^a \right)^{1/a}.$$

Note that EUD is a scaled version of the a -norm of the dose to the particular structure, and hence is known to be a convex function for any $a \geq 1$ and concave for $a \leq 1$. Thus, the problem

$$\begin{aligned} \max_w \quad & \text{EUD}_a(D, T) \\ \text{s.t.} \quad & D_{(i,j,k)} = \sum_{A \in A} d_{(i,j,k),A} w_A, \quad \forall (i,j,k) \in \Omega, \\ & \text{EUD}_b(D, S) \leq \phi, \\ & \text{EUD}_c(D, N) \leq u, \\ & 0 \leq w_A, \quad \forall A \in A. \end{aligned}$$

is a convex optimization problem provided $a \leq 1$ and $b, c \geq 1$. As such, locally convergent NLP algorithms will find globally optimal solutions to these problems.

Beam Angle Selection and Wedge Orientation Optimization. Optimization also lends itself to solving the more complex problem of selecting which angles and wedge orientations to use, as well as their intensities. Mixed integer programming (MIP) is a straightforward technique for these types of problems. We describe an optimization model that simultaneously optimizes beam angles, wedge orientations, and beam intensities. Wedges are placed in front of the collimator to produce a gradient over the dose distribution and can be effective for reducing the radiation dose to organs-at-risk. This can be done by adding an extra dimension F to the variable w_A :

$$\begin{aligned} \min_{w, \psi} \quad & \lambda_t f(D_T) + \lambda_s f(D_S) + \lambda_n f(D_N) \\ \text{s.t.} \quad & D_\Omega = \sum_{A,F} d_{\Omega,A,F} w_{A,F}, \\ & w_{A,F} \leq M \cdot \psi_A, \\ & l \leq D_T \leq u, \\ & \sum_{A \in A} \psi_A \leq K, \\ & \psi_A \in \{0, 1\}, \quad \forall A \in A. \end{aligned} \tag{4}$$

The variable ψ_A is used to determine whether or not to use an angle A for delivery. The

choice of M plays a critical role in the speed of the optimization; further advice on its choice is given in Lim *et al.* [5].

Solution Techniques. Simulated annealing (SA) has been well accepted in the medical community [14]. But, the weakness of SA is its inability to verify the optimality. On the other hand, it is possible to find a global optimal solution for Equation (4). However, due to its slow convergence, using the MIP model has not been very useful for designing a treatment plan in the hospital. Recently, Lim *et al.* [5] proposed an iterative solution approach that solves the MIP problem fast (within 20 min for two clinical case examples presented). It is termed a *three-phase approach*.

Three-phase approach is a multiphase technique that “ramps up” to the solution of the full problem via a sequence of models. Essentially, the models are solved in increasing order of difficulty, with the solution of one model providing a good starting point for the next. The models differ from each other in the selection of voxels included in the formulation, and in the number of beam angles allowed.

If the most promising beam angles can be identified in advance, the full problem can be solved with a small number of discrete variables. One simple approach for eliminating unpromising beam angles is to remove those passing directly through any OAR [15]. A more elaborate approach [16] introduces a score function for each candidate angle, based on the ability of that angle to deliver a high dose to the PTV without exceeding the prescribed dose tolerance to OAR or to normal tissue located along its path. Only beam angles with the best scores are included in the model. Although there is no guarantee that this technique will produce the same solution as the original full-scale model (4), Lim *et al.* [5] have found that the quality of its approximate solution is close to optimal based on several numerical experiments.

Intensity Modulated Radiation Therapy

Background. *IMRT* is a high-precision radiotherapy that has been extensively used to treat a range of cancer types since the 1990s. As an advanced form of the

Figure 3. A multileaf collimator (MLC) for IMRT.

state-of-the-art 3DCRT and thanks to the continuous development of treatment techniques, IMRT is able to deliver more accurate radiation dose to precisely conform to the three-dimensional shape of the tumor while sparing the surrounding normal tissues. That is because the advanced MLC can move its leaves back and forth to block the portion of each beam's radiation dose (see Fig. 3). This capability allows the MLC to divide its *aperture* into hundreds of rectangular grids, and thus partitioning each beam into *sub-beams*, also called *beamlets* or *pencil beams*, from which the radiation is modulated. Therefore, a high degree of flexibility in delivering radiation dose distribution from each beam angle can be achieved by IMRT.

The IMRT treatment planning optimization framework typically consists of solving three sequential problems: beam angle optimization (BAO), fluence map optimization (FMO), and beam segmentation (BS). Assuming the geometry information of the treatment volume and prescribed dose to the target have been obtained. The (BAO) problem aims to find a subset A^* of a given set A of candidate beam angles ($A^* \subset A$) to deliver a satisfactory treatment. FMO aims to find an optimal beam shape intensity map, or known as a *fluence map* for each selected treatment angle. The fluence map specifies the intensity of radiation dose of each beamlet within a beam. Note that evaluating a BAO solution requires the knowledge of optimal fluence map for each selected angle;

hence, the BAO problem always combines FMO together. In BS, the interest is to decompose the fluence map into a minimum number of implementable MLC apertures and minimum corresponding intensities. These three problems have invited substantial research effort on optimization models to facilitate IMRT treatment planning in recent years.

Beam Angle Optimization and Fluence Map Optimization. With the patient lying on the treatment couch, the gantry of the linear accelerator can rotate 360° in a plane perpendicular to the couch. It stops at one angle to deliver certain amount of radiation. If we only allow the movement of the gantry during treatment and it is possible for the gantry to stop and deliver radiation at any angle, say every 1° , there are a set (A) of 360 beam angles available from which a BAO model aims to find an optimal subset ($A^* \subset A$) of angles that can yield best treatment. An FMO model determines the optimal fluence map for each selected angle.

As we discussed, the MLC discretizes a 2D beam into a matrix of grids. Let us define the beamlet intensity or weight as $W_{a,l,p}$, which is continuous and denotes the intensity of radiation delivered by the beam angle a and through the (l,p) th beamlet, $l = 1, 2, \dots, m$, $p = 1, 2, \dots, n$ (m is the number of MLC leaves, and n is the number of discrete units that a leaf can move). Also, the 3D treatment volume is discretized into thousands of voxels (i,j,k) . We term $d_{i,j,k,a,l,p}$ as the dose delivered by the beam angle a through the (l,p) th with a weight of 1 beamlet and received by voxels (i,j,k) . Thus, the total dose $D_{i,j,k}$ deposited in a voxel (i,j,k) is

$$D_{i,j,k} = \sum_{a,l,p} (\omega_{a,l,p} \cdot d_{i,j,k,a,l,p}). \quad (5)$$

Since the optimal set of beam angles are intimately related to the optimal fluence map for each angle, these two problems must be dealt with together in the problem formulation. Let a denote an angle, $a \in A$; then, formulating an optimization model for optimizing both beam angles and the fluence maps is a simple extension to Equation (4) that we discussed for the conventional 3DCRT, and the model can be obtained by

replacing the dose calculation constraint and big-M constraint in Equation (4) with constraints (6) and (7) as follows:

$$D_\Omega = \sum_{a,l,p} d_{\Omega,a,l,p} w_{a,l,p}, \quad \Omega = \{T \cup S \cup N\}, \quad (6)$$

$$w_{a,l,p} \leq M \cdot \psi_a. \quad (7)$$

See more details of this formulation and others in Lim *et al.* [17].

Obtaining global optimal solutions is difficult due to the computational complexity of the problem. Therefore, a good deal of heuristic methods has been discussed in the literature. Pugachev and Lei [18] introduced a scoring-based approach. Li *et al.* studied a particle swarm algorithm [19] and genetic algorithms [20]. Lim *et al.* [17] developed a *LP-based iterative beam angle elimination* (IBAELP) algorithm to obtain quality beam angles with optimized fluence maps. Aleman *et al.* [21] discussed a neighborhood search algorithm.

Optimal Beam Segmentation. An IMRT treatment plan can be completed by solving BAO and FMO problems. However, the deliver of the plan requires another optimization process, that is, solving the beam segmentation problem. In each beam angle, the MLC need to be configured to generate a series of apertures to deliver the given fluence map. Therefore, the BS problem aims to decompose the fluence map into a set of implementable MLC apertures and corresponding intensities. The number of delivering apertures associates with MLC setup times, while the intensity for each setup results in the length of beam-on time. The objective of the BS optimization consists of minimizing the two kinds of time simultaneously.

In a BS optimization model, the fluence map $\mathcal{W}$ is often represented from real matrix to integer matrix, that is,

$$\mathcal{W} = \begin{pmatrix} w_{1,1} & w_{1,2} & \cdots & w_{1,n} \\ \vdots & \vdots & \ddots & \vdots \\ w_{m,1} & w_{m,2} & \cdots & w_{m,n} \end{pmatrix},$$

where $w_{l,p} \in \mathbb{Z}$, for $l = 1, \dots, m$, $p = 1, \dots, n$. Suppose that there are K binary matrices S^k and K integers μ_k . Suppose that K denotes the maximum number of different apertures needed to deliver the required fluence map, S^k represents the k th aperture profile, and μ_k represents the number of unit delivery time for the k th aperture. The primary requirement or constraint to the model is

$$\mathcal{W} = \sum_{k=1}^K \mu_k \cdot S^k, \quad (8)$$

where $S^k = [s_{l,p}^k]$, $s_{l,p}^k \in \{0, 1\}$, $l \in \{1, 2, \dots, m\}$, $p \in \{1, 2, \dots, n\}$, $\mu_k \in \mathbb{Z}$, $k \in \{1, 2, \dots, K\}$. Another important constraint required by the MLC movement is that the element in each row of S^k cannot change more than two times starting from one side to another side, also known as *consecutive one property*. For example,

$$0 \ 1 \ 1 \ 1 \ 0$$

is a feasible sequence. But,

$$0 \ 1 \ 0 \ 1 \ 0$$

is not allowed because the sequence of ones is not continuous.

There are two objectives of the BS model:

1. Minimize K , (setup time);
2. Minimize $\sum_{k=1}^K \mu_k$ (beam-on time).

The BS problem has been well studied so far. If the optimization model adopts the single objective of beam-on time, the problem is relatively easy and can be solved in polynomial time [22–24]. However, the problem is proven to be *strongly NP-hard* [23] when both objectives are included, that is, minimizing the total treatment time. Therefore, both researchers and planners use various heuristics. Engel [25] proposed an efficient algorithm that generates optimal beam-on time, but the optimality of setup time (K) is not guaranteed. Lim and Choi [26] proposed a two-stage IP approach that improves setup time with smaller values comparing Engel's approach, yet no proved optimality is present. Both methods claimed that solving problems

with a matrix size larger than 10×10 takes less than few seconds. Taskin *et al.* [27] developed a decomposition approach using MIP to obtain exact optimal solutions.

Proton Therapy

Introduction. Proton therapy is another form of radiation delivery method for cancer treatment. Thanks to continuous research and development of proton therapy for years; it is revealed that the radiation therapy with proton beams may perform a more precise dose delivery than widely used current practice of radiation treatment with photon beams in certain types of cancer. It is because the dose distribution from a monoenergetic beam of protons has an entrance region of slowly rising dose followed by a sharp increase, called *Bragg peak*, near the end of range. By superimposing beams of different energies, the Bragg peak can be spread to generate a dose distribution that provides moderate entrance dose, uniform high dose within the target tissue, and almost zero dose beyond the target (see Fig. 4). Highly conformal dose distributions with low integral dose can be achieved with a small number of proton treatment fields convergent on a target region.

IMPT Treatment Planning and Optimization. There are four modulation methods for radiation therapy formally defined by Lomax [28]:

two-dimensional (2D) modulation, distal edge tracking (DET), two-and-half-dimensional (2.5D) modulation, and three-dimensional (3D) modulation. The 2D (in the beam's-eye-view) modulation technique modulates the intensities or weights of spread-out Bragg peaks (SOBPs) with fixed extents. The DET technique modulates the intensity of single Bragg peaks with depths according to the distal edge of the target volume. The 2.5D modulation technique modulates the intensity of SOBPs with variable extents. The 3D modulation technique modulates the intensity of all Bragg peaks located within the target volume, which adds one additional dimension (depth) to the 2D modulation. The 3D modulation is performed by the pencil beam scanning (or called *spot scanning*) technique [29]. Their test results suggested that the 3D modulation may be superior in target coverage and sparing normal tissues than other methods. We consider 3D intensity modulated proton therapy (IMPT) treatment planning in the following discussion.

Unlike IMRT research, the study of IMPT treatment planning and associated optimization algorithms is in its beginning stage. There are various delivery techniques and identified system-specific optimization problems within IMPT treatment planning, or general proton therapy, are more clinically oriented. Therefore, most current research papers are primarily contributed

Figure 4. A comparison of the amount of radiation delivered with conventional photon beam radiation therapy versus proton therapy. Conventional therapy is distinguished by a relatively high entrance dose and an exit dose. By contrast, proton therapy has a much lower entrance dose and no exit dose.

by clinical researchers, while few are done by optimization experts. General IMPT treatment planning optimization problems are discussed in following paragraphs.

Beam Intensity Map Optimization. The beam (or spot) intensity map optimization problem is to determine the optimal intensity or weight of each beam spot within the three-dimensional target volume with the objective of achieving prescribed dose as close as possible. Two preliminary steps before performing the intensity map optimization includes (i) selecting the number and direction of treatment beam angles, and (ii) defining the spot position for each field. These two can be separate optimization problems.

The intensity map optimization problem for IMPT planning is essentially equivalent to conventional IMRT treatment planning, in which intensities of pencil beams need to be optimized for each treatment angle. Therefore, optimization methods used for IMRT intensity map can be adapted to IMPT use. The objective function (for minimization) can be the total deviation between prescribed dose and delivered dose, and dose constraints can be assigned to the model, for instance. The IMPT treatment planning system at Paul Scherrer Institute (PSI) uses an iterative least-square optimization approach [28]. Pflugfelder *et al.* [30] at German Cancer Research Center (DKFZ) conducted a study comparing with three optimization algorithms including steepest descent, conjugate gradient, and quasi-Newton methods.

Beam Direction Optimization. Currently, the selection of the number of beams and their directions, that is, the beam direction optimization problem, are manually performed by physicians based on their judgment, both for proton and photon beams. Unlike conventional IMRT with photons, the beam direction optimization algorithm has not been well documented for IMPT treatment planning. Some studies discussed the effect of the beam number and direction selection based in their case studies [28,31]. Since the beam direction optimization problem is typically a large-scale combinatorial problem, solution algorithms are often computationally expensive.

Beam Scanning Path Optimization. The beam scanning path optimization for IMPT treatment planning is to identify the optimal scanning path to deliver small proton pencil beams. Given the optimized spot intensity and predefined spot geometry in each treatment field, a scanning path that connects all scanning spots needs to be determined, so that the pencil beam can move continuously or discretely according to the path. The objective function to this problem can be formulated as the total length of the scanning path, which is meant to find minimal treatment time. Kang *et al.* [32] proposed a traveling salesman problem (TSP) formulation and a simulated annealing algorithm to solve this problem. Trofimov and Bortfeld [33] discussed the beam sequencing issues in a raster continuous scanning system.

Treatment Planning with Uncertainty. There are two main reasons to account for uncertainty in IMPT treatment planning. First, protons are physically very sensitive to inhomogeneous tissues when they pass through the patient's body. Range uncertainties may occur and result in misplacing Bragg peaks and deviating dose distribution from prescribed dose. Secondly, IMPT treatment plans, especially by the 3D modulation, are particularly sensitive to organ motions because the Bragg peaks require precision in millimeters. It is easy to result in delivering very high dose on normal tissues but very low dose on target. Therefore, treatment planning optimization with consideration of uncertainties is crucial for achieving better quality and robust IMPT treatment plans. A series of related studies have been reported and different uncertainties such as system errors, organ motion, patient positioning are discussed in Morávek *et al.* [34], Peterson *et al.* [35], and Pflugfelder *et al.* [36].

BRACHYTHERAPY

Background

Brachytherapy is an internal (invasive) radiation therapy modality that has been solely used or combined with external

radiation therapy to treat certain cancers such as prostate. In *brachytherapy*, radioactive substances are placed within or close to the tumor region in the form of wires, seeds, or rods. Types of brachytherapy are categorized depending on how the radioactive sources are placed inside the body, and include interstitial brachytherapy, intracavitary brachytherapy, intraluminal radiation therapy, and radioactively tagged molecules given intravenously. Interstitial brachytherapy is the focus of this section.

The problem of brachytherapy treatment planning (BTP) is primarily to determine the implantation location of radioactive sources. The goal of a brachytherapy plan consists of delivering enough radiation dose to the target tumor mass and sparing surround critical organs and normal tissues. Obtaining true optimal treatment plans for BTP is also extremely difficult in a clinical setting. Therefore, optimization models have been developed to find near optimal solutions within a clinically acceptable time [37,38].

Optimization Models

Modeling the BTP problem firstly requires the dose calculation scheme. Meyer *et al.* [38] described an approximation function for dose rate. Let us term the dose rate at a distance l from a single source as $D(l)$, referring to Meyer *et al.* [38] for calculations. Then, if j indexes the three-dimensional grid of prespecified possible locations of radioactive sources, where $j = 1, \dots, m$. For an arbitrary point i , the total dose at point i from all source locations is given by

$$D_i = \sum_{j=1}^m y_j D(l_{ij}), \quad (9)$$

where y_j is a binary vector indicating the selection or nonselection of location j , and l_{ij} is the Euclidean distance from point X_i to point X_j , that is, $l_{ij} = \|X_i - X_j\|$.

The constraints and objective of the BTP optimization model are homogeneously constructed as the RTP model. One can control the dose of radiation on PTV by hard

constraints:

$$D_i \leq T_U, \quad (10)$$

$$D_i \geq T_L, \quad (11)$$

where T_U and T_L are upper and lower bounds for dose deposition on PTV; or soft constraints:

$$D_i - R_U^T \leq T_U, \quad (12)$$

$$D_i + R_L^T \geq T_L, \quad (13)$$

where R_U^T and R_L^T are dose deviations from upper and lower bounds.

The specified maximum number of locations for seeds can be controlled by this constraint:

$$\sum_{j=1}^m y_j \leq \text{maximum number of locations.} \quad (14)$$

The objective functions may vary based on treatment planner's preferences. Lee *et al.* [39] described two kinds of objective functions. One minimizes the total dose deviation on PTV, and the other maximizes the total number of points that satisfying specified dose distribution requirements. Certainly, most objectives that are studied in external radiation therapy treatment optimization models can also be utilized to brachytherapy.

Solving the above BTP models in the clinical setting is still an ongoing research. Solution methods can be divided into two groups. One is an exact algorithm mainly of the branch-and-bound. Meyer *et al.* [38] tested various combination of branch-and-bound strategies of one commercial optimization solver. Cutting planes and problem preprocessing are also suggested to reduce the computational difficulty of BTP models. Another group of methods are heuristics such as SA and genetic algorithms [39].

In addition to the location problem, another optimization problem in BTP is to decide an appropriate amount of time (dwell time) for those sources staying in patient's

body [40]. In the dwell time optimization model, the dose calculation is defined as

$$D_i = \sum_{j=1}^m t_j D(l_{ij}), \quad (15)$$

where t_j is the dwell time. The constraints including (14)–(17) and objective functions for optimizing locations of radioactive sources can be used to optimize dwell time. Alterovitz *et al.* [40] introduced an LP formulation to the problem. Its solutions were compared with ones from the SA approach implemented in the clinical setting. Detailed discussions of their model can be found in Alterovitz *et al.* [40].

CHEMOTHERAPY

Chemotherapy or drug therapy uses drugs to control and even cure the cancer by minimizing tumor cells in certain treatment periods [41]. Although chemotherapy has been extensively used to treat cancer, it is well-known for its side effects; it brings not only efficacy to the tumor control, but also toxicity to normal tissues. Hence, the chemotherapy plan is often designed with two objectives: minimizing the tumor mass and minimizing the total drug dose [42], and to determine the schedule of drug treatment cycles and the amount of drug dose in specific cycles. Since there are very complex biological processes in patient's body during the drug treatment, it is difficult to achieve an optimal chemotherapy plan.

Many optimization approaches have been developed to improve the efficacy of chemotherapy [7, 41–43]. We take a typical chemotherapy planning optimization model given by Agur *et al.* [7] for illustration in three components as follows:

First, a simulation algorithm is used to predict body's response to chemotherapy. Two types of human cells are considered: *host cell* and *target cell* (tumor cell). The aim of the treatment is to reduce the target cells and maintain a certain level of host cells in patient's body. The growth of both cells can be interfered by chemotherapy. When the cells are at their sensitive life cycle and exposed to chemotherapy, they could

probably die. With the help of well-done biological studies, the cell behavior during chemotherapy is modeled by the simulation algorithm.

Secondly, the objective function named as fitness function is developed mainly based on the level of host and target cells that reflects the treatment plan performance. The primary variable of the fitness function is the chemotherapy treatment schedule over a series of n time intervals, which are represented by a vector of binary numbers. Let $\mathcal{F}(\mathbf{s})$ denote the fitness of a treatment schedule $\mathbf{s}$. It can be briefly constructed as follows:

$$\begin{aligned} \mathcal{F}(\mathbf{s}) = & c_1 x_h(\mathbf{T}) + c_2 x_a(\vec{T}) + c_3 I_{\text{alive}} + c_4 I_{\text{cure}} \\ & + c_4 t_{\text{death}} + c_5 t_{\text{cure}}, \end{aligned} \quad (16)$$

where $x_h(\mathbf{T})$ and $x_a(\mathbf{T})$ denote the levels of host and target (abnormal) cells at the end of time period $\mathbf{T}$, I_{alive} and I_{cure} denote the indicators of patient's condition being alive or cured at the end of treatment, t_{death} and t_{cure} denote the time of death or cure eventually, and c_i for $i = 1, \dots, 5$ denotes the weighting factor.

Suppose that one means the treatment is given and zero means the treatment is not given in a time interval. For example, the vector $s = (1, 0, 1, 1, 0, 0, 1, 1)$ indicates an eight-hour treatment schedule if the time unit is an hour, where the patient receives the treatment in the first hour, and stops taking it in the following hour, then continues the treatment for consecutive two hours, stops two hours, and continues another two-hour at the end. After a treatment schedule is fulfilled, the fitness function is evaluated to assess the condition of the patient, that is, cured, survival, or death.

Thirdly, the local search heuristics can be used to solve the problem. Overall, the aim is to find a good solution within computational capability.

CONCLUSIONS

Soon, cancer is projected to be the leading cause of death in the United States. Optimization techniques have been playing a key

role in facilitating cancer treatment planning and delivery. Well-designed optimization models can not only improve the treatment accuracy but also help save health-care cost by more efficient treatment delivery. We have described various cancer treatment optimization models and their solution methods in this article. The aim was to give a brief overview about recent advances in cancer treatment models. This is an area of research that requires multiple disciplinary collaborative efforts among engineers, mathematicians, computer scientists, physicians, physicists, and more. We truly hope that cancer becomes history in our generation.

OPTIMIZATION OF PUBLIC TRANSPORTATION SYSTEMS

JUAN CARLOS MUÑOZ

de Chile, Santiago, Chile

INTRODUCTION

Public transportation systems pose a highly complex set of challenges for the analyst that stem fundamentally from their sheer size. The task of scheduling a transit network involves determining the operations of thousands of vehicles and drivers making daily trips, often numbering in the millions. A prime example is the Interligado system in Sao Paulo, Brazil, which handles 9 million trips per day on approximately 14,000 vehicles. In the United States, more than 20 cities operate fleets of over 1000 buses [1]. The design, planning, and operation of a transit system must also address an array of other considerations including the structure of the network, its coexistence with other existing transportation systems, the congestion created by its use (which in turn effects service levels), and the autonomy on travel decisions of users, the system's lifeblood.

In light of these considerations, transit systems are typically analyzed from the opposing perspectives of demand and supply.

Demand

The demand for transit trips arises from the spatially distributed needs of individuals in accessing destinations at times that may be specific (e.g., travel to work) or flexible (e.g., shopping trips) and for which there is a certain maximum willingness to pay. This demand typically has a spatial and temporal structure that exhibits time-of-day variations that are clearly marked off into peak and off-peak periods. How demand translates into

actual trips depends on the levels of service supplied by the transit system (and alternative transportation modes, if any) and how they are perceived by users. If service levels are deficient, some potential trips shift to alternative modes or may not even be made at all. Any trip demand study thus requires an understanding of how demand is distributed across the service area, how it breaks down across different user socioeconomic strata, what transportation modes are available for each user (taking account of motorization rates), what are the purposes of the trips, and what attributes of the transit and alternative system services impact users' decisions (e.g., walking time, wait time, in-vehicle time, number of transfers, fare, comfort, reliability, safety, security, level of information, and seat availability).

Supply

Transit supply is expressed by the availability of *services* or *routes* to those willing to travel. Each service has a specific starting and ending place and follows a sequence of stops. Also, each service has a load limit (passenger capacity) and is therefore subject to congestion, implying that service levels begin to decline as usage increases. Congestion on public transit systems is manifested in terms of wait time increases due to fully loaded vehicles passing up waiting riders, longer boarding and alighting times at stops or stations, deterioration of comfort level aboard vehicles, and so on.

Most urban transit systems coexist with other transportation modes. The road infrastructure required by surface transit modes is often shared with flows of cars, motorcycles, bicycles, and trucks, complicating the design of transit networks and impacting its performance.

The sequence of decisions constituting the transit operations planning process for the supply of service is depicted by the flowchart in Fig. 1, adapted from Ceder and Wilson [2] and Ceder [3]. In practice, the boundaries between the various stages are somewhat

Figure 1. Transit operation planning process.

blurred and the process is enriched by feedback on previous decisions. Feedback is also employed in analyzing the impacts on subsequent stages of modifications to earlier ones.

According to this scheme, the design and analysis of a public transit system can be structured into four decision levels as follows.

Strategic decisions are those which are difficult to modify later, at least for relatively lengthy periods. Examples of such decisions are the transit mode (e.g., BRT versus LRT versus Metro); the type of vehicle to acquire (capacity); the structure of services to be offered; and, at a lower level, the location of stations and stops along the routes.

Tactical decisions are those that hold over the medium term and are revised anywhere from monthly to half-yearly. They include adjusting service frequencies at each period,

modifying fares, and offering operational variations on services such as deadheading, expressing, and short turning. In a two-way service, when demand for service is significantly imbalanced, a *deadhead* operation could prove beneficial. In such a case, transit vehicles would operate normally, loading passengers, on the high-demand direction and return empty (and as fast as possible, maybe using a different path) on the opposite direction. Such a scheme increases the supply where it is most needed while decreasing it in the low-demand direction, allowing for a balanced occupation rate of the vehicles in both directions. An *express* service is a service that skips some predefined stops, offering a fast trip to its passengers. A *short-turning* service associated with a certain route consists of providing a shorter service that operates only

in a section of the route with the purpose of increasing supply in its busiest section.

Operational decisions, such as drivers' shifts, and route and vehicle assignments, typically occur in the short term (daily basis).

Finally, control decisions define the system's recovery response to the inevitable disruptions that upset service schedules such as absent drivers, vehicle breakdowns, services running late, vehicle bunching, and so on.

In this article we discuss how operations research provides answers to the problems confronting each type of decision. The text is structured around the four decision-making levels: strategic or long term in the section titled "Strategic Decisions," tactical or medium term in the section titled "Tactical Decisions," operational or short term in the section titled "Operational Decisions," and disruption response or real-time control in the section titled "Real-Time Control." A deeper perspective of all these issues can be found in Vuchic [4].

STRATEGIC DECISIONS

This decision level deals with questions relating to the formal design of a new and complete transit system (a "greenfield" project) or the modification of an existing one. An example of a city designed and implemented from the ground up is Brasilia, created in the mid-twentieth century, but it was initially mostly designed for cars. Other cities have faced the challenge of drastically changing a transit system already in place [5]. In either situation, strategic decision making needs to address the following questions:

1. The market structure that will govern the system. How many operators will participate in the system? Will it be based on private operators? Do you expect operators to compete for the passengers? What role will the government have? Different cities have tried different approaches, from full deregulation and fully privately operated to a centralized system run by the government. In between, there are centrally operated systems with private operators such as Transmilenio in Bogota. In addition, these decisions are influenced by the institutional framework chosen by the government, for example, different agencies in charge of different modes (e.g., buses and metro) or a single agency in charge of the complete system, such as transport for London. The answers to these questions probably have significant impacts on the systems costs and the quality of service faced by the users.
2. The transportation modes that will configure the system (metro, light rail, BRT, and regular buses). For surface modes, it is important to define the level of interaction that the system will have with other modes, particularly private cars. The more exclusive is the transit right-of-way and the smoother is the boarding and alighting process, the higher will be the vehicle speeds, generating significant benefits in terms of level of service to users. Also essential is the definition of the type of energy to be used by the vehicles, since once decided it can be very costly to change. Note that per passenger transported, the transit system is less polluting than cars; so it is intrinsically associated with a more sustainable motorized urban mobility. Still, in many cities the transit system as a whole is a major actor in the generation of pollution (atmospheric and acoustic).
3. The type of route structure of the transit network. This decision is intimately linked to the level of fare and operational integration between the routes. If there is no fare integration, many of the routes will tend to be designed to cross the entire area served so that most riders can reach their destinations paying a single fare. Such routes tend to be inefficient given that along most of their length, vehicle load factors are relatively low. This oversupply of underutilized vehicle kilometers can be reduced by adopting a system design that ensures integration between routes. Typically, the design is a trunk-and-feeder system in which trunk services cover large distances

at high speeds and high vehicle load factors while feeder services shuttle to and from the trunk lines, picking up riders at their origin points and delivering them at their final destinations. This setup significantly reduces fleet and operating costs but forces users to transfer. It also requires a road infrastructure and right-of-way that enables high operating speeds along transit corridors with stops or stations that can efficiently handle transfers on a large scale. Varying levels of route integration are observed in transit systems around the world, including total competition among different vehicles on a single route, competition among different routes, competition among different modes, and total fare and operational integration.

4. The specific routes to be supplied. It is necessary to determine for each route its actual path or course, the type of vehicle, and the service frequency. At this decision level the analysis is typically confined to the highest demand periods of the day.

In responding to these challenges, planners attempt to identify a configuration that maximizes social welfare, this being defined as the total benefits of trips undertaken less the social cost of the system in terms of resources allocated by society as a whole to enable transit users to reach their chosen destinations. Of course, quite often this maximization procedure is restricted to satisfy some kind of budget constraint. Typically, this process involves building a model that represents overall generalized costs for a fixed and known level of transit trip demand specified by a trip matrix of travel between different zones of the area served. The following types of costs should be included:

1. *Costs That Reflect Impacts on Users.* Among the direct impacts of a trip are walking time (i.e., stop or station access time), waiting time at each stage of the trip (including added time when waiting users are passed up by fully

loaded vehicles), the disutility of transfers, and in-vehicle travel time. Vehicle load factors should also be considered for their effects on passenger comfort. In the case of high-frequency services that are not operating to a set schedule, waiting time is assumed to be inversely proportional to frequency. The fare is not included as a social cost since it is a mere transfer from one element of the system (the user) to another (the vehicle operator) rather than the consumption of a resource.

To attach cost figures to these impacts, the value of each of them—access time, waiting time, and penalties for transfers and overcrowding—must be determined. These values greatly vary from user to user if they are estimated on the basis of wage rates, but the use of a common value for all riders is recommended so that the model is not biased toward those with greater purchasing power (who highly value time). It is up to the transit authority to define the value of time, but it should be noted that the higher is this value, the denser will be the network design and the more frequent will be the services. It is therefore an extremely important decision that is typically grounded on how significant a role the transit system is expected to play in the city.

2. *Infrastructure Costs.* Different transit technologies and services require different levels of capital investment. Putting a value on these costs necessarily means defining the number of stops or stations, the level of segregation of the bus lanes, and the expenditures involved in building and equipping the corridor. The cost of installing any vehicle control equipment or traffic signal priority systems must also be included. Each of these decisions directly impacts on the operating speed of services.
3. *Operation Costs.* These typically include the cost of fleet acquisition and a unit operating cost per run for each route (for a given type of vehicle). By a *run*, we understand the trip made by

a single vehicle from the beginning to the end of a route.

4. *Costs Imposed by Externalities.* This includes impacts on travel times of other transportation modes (cars, bicycles, and walking), impacts on accident rates, atmospheric and noise pollution, and so on.

The formulation should model demand as a set of trips where each user chooses the best alternative available. In the absence of congestion or vehicle load (capacity) limits, such a set can be identified simply by minimizing the social costs of the system.

If congestion in the system is expected to be significant, however, with vehicle load levels close to maximum capacity, the model will have to accommodate this added complexity. A design that omits this factor and merely minimizes total costs would wrongly assume that riders spontaneously choose the alternative that is best for the system and not just for them. Consider, for example, the simple case illustrated in Fig. 2 of a transit corridor with two lines in which their frequencies need to be determined. The corridor has three nodes and two origin–destination pairs (A–B, A–C).

Let us assume that line 1 is very fast along its entire length but has high operating costs while line 2 is slow but with low costs. Both lines charge the same fare. Clearly, the frequency on line 1 cannot be zero since it is the only route supplying trips from A to C and, since it is offered, A–B passengers will also want to take it. But if a capacity constraint for line 1 were active, it could be cheaper for the system to have A–B passengers to travel on the slower line than to increase frequencies on the faster one, in which case the model would indicate that they wait for Line 2, something they would not do of their own accord.

Figure 2. Corridor with two O–D pairs served by two lines.

Thus, if capacity constraints are included, the design must analyze how users decide their route when there is more than one alternative, each with its own combination of times, transfers, and fares. Models of user behavior need to take into account that riders normally place a higher value on waiting than walking and more value on walking than in-vehicle traveling [6]. They must also consider that these values greatly vary between users of different income levels.

Incorporating all of these different elements into a model is no easy task, and often some are left out of preliminary design versions. Nevertheless, it is important that the model accurately represents the transit system so that it can generate detailed scenarios for comparing alternatives and supporting decision making.

Certain other indicators are useful in providing general orientation for the various decisions confronting transit planners. For example, it can be shown that the optimal service frequency (f^*) of a route with no capacity or budget restraints is given by the following formula [7,8]:

$$f^* = \sqrt{\frac{k c_w q}{c_o}}, \quad (1)$$

where c_w is the value of wait time, q is the arrival rate of passengers to the system, c_o is the operating cost per run, and k is a headway constant defined so that $k = 1/2$ if headways are perfectly regular and grows as they become increasingly irregular. This formula can be used to deduce the effect of an abrupt decline in operating costs or a rise in demand on the optimal route frequency. Note, however, that in developing countries the service frequencies given by Equation (1) may be insufficient to meet demand. This is because the value of operating costs tends to be much higher than of wait time, implying $c_o \gg c_w$. In such cases, the frequencies will have to be adjusted to ensure that demand on the most heavily traveled segment of each route is satisfied.

The lower bound for the number of transit vehicles required during peak periods, n ,

can also be estimated from the service frequency if we recall that $n = \frac{t_c}{h}$, where t_c is the cycle time, h is the headway, and $h = \frac{1}{f}$. The *cycle time* on a two-way service is the amount of time needed by a vehicle to do both services sequentially, returning to its original position.

This type of analysis can further be utilized to determine the flows over a transit corridor that would justify the adoption of different transit solutions. Replacing a regular bus route with a BRT or a Metro line, for example, is an important question that many decision makers must face given the large investment involved (the per-kilometer cost of a metro line is at least US\$60 million and can reach as high as several hundred million) and many actors attempt to influence these decisions.

Often planners attempt to formulate the problem of deciding which technology should be considered for different demand levels. These simplified results must be applied with caution, however, as travel patterns of similar size but different structure (in average trip distance, for example) may or may not justify a decision such as that mentioned in the previous paragraph. In general, however, decisions should not be made on the basis of a subset of a network without considering its global structure, particularly in the presence of heavy congestion.

It should also be recalled that in reality trip demand is far from being fixed and known as we assumed above. Forecasting demand is a complex process that depends on many factors related to the characteristics of the various transportation modes and of the users themselves. Moreover, any changes to a transit system that impact perceived service levels may affect the number of trips taken not only by current users but by potential ones.

Finally, decisions at this level must determine the system's fare structure and method of payment. The fare structure influences users' route choices within the network. The higher is the charge for transfers, for example, the greater will be the proportion of users opting for direct routes even if other itineraries are faster.

TACTICAL DECISIONS

Once the routes to be served and the size of the system's fleet have been decided at the strategic level, the planning process turns to the tactical decisions. The issues addressed at this level are as follows:

1. The definition of regular operating periods. Travel pattern data are used to determine sequences of hours during which trip volumes and their space and time characteristics are relatively homogeneous.
2. As already noted, service frequencies for peak periods are normally defined at the strategic level and serve as the basis for identifying the size of the vehicle fleet required by the system. The frequencies for all other periods are defined at the tactical level. For this purpose, it is assumed that the demand for trips is known and that the frequencies can be obtained by Equation (1). More sophisticated methods for determining frequencies that incorporate variable and/or elastic demand assumptions, alternative concepts of waiting time, and explicit budget restraints are reviewed in Ceder [3]. The ongoing adjustment of frequencies at this decision level should keep them in step with observed demand levels in the system, and the expected demand pattern changes because of seasonal factors such as holiday periods or special events that attract large crowds to specific locations.
3. The definition of schedules based on the frequencies for each period. This involves determining the departure times from each terminal for each route. As a general rule, if demand is relatively uniform over a given period the departures are scheduled to maintain equal headways. If demand varies significantly, on the other hand, departure times can be adjusted so that passenger load levels are equalized over the most heavily used segment of a route. The problem is considerably more complex if it is desired

to synchronize transfers between different routes at transfer stations. Recent work on this issue is reviewed in Desaulniers and Hickman [9].

Given expected between-stop travel times and dwell times across the network for each period, the visit times of each run at each stop and arrival times at route terminals can be predicted. This result is central to vehicle scheduling as it determines the time when a vehicle becomes newly available for service after finishing a run.

For low-frequency routes (less than six vehicles per hour), schedules are normally published in various media so that users can plan their stop arrival times to minimize waiting. With high-frequency routes, schedules are rarely published, as the inevitable variations in actual service relative to the scheduled service intervals are relatively large, rendering detailed timetables of little practical use to riders. They may still be used by drivers as a general guide for maintaining regular intervals between successive runs.

4. Definition of special services for high-demand periods or routes with high spatial concentration. Implementation of such services, for example, short turning, deadheading, and express services may be justified by certain demand structures. A number of these strategies are discussed in Furth and Day [10].

One of the advantages of these services is that they constitute an alternative to putting on additional vehicles and thus reduce the required fleet size for serving a given demand, which in turn implies lower system costs. In operational terms, these strategies increase frequencies along high-load route segments to reduce wait times. Express services in particular are used to reduce the in-vehicle travel times of some trips.

5. Establishment of fares for each period. Fare structures can be defined to promote or discourage ridership at different times of the day. For example, since the number of required vehicles is

necessarily determined by the highest demand period, a means of reducing fleet size is to raise fares for peak hours, which tends to flatten the peak as some users shift their travel plans to lower fare off-peak periods. Fare variations can also be applied to different directions of the same route. Charging a higher rate on the high-demand direction will encourage greater use of services at points where there is more available capacity. Also, fares should depend on the distance traveled to represent in some sense the cost imposed on the system. If the exact distance cannot be measured, charging according to a zonal structure may provide the second-best alternative.

OPERATIONAL DECISIONS

Given the route schedules and available resources in terms of vehicles, drivers, garages, and possible driver relief points, the scheduling of vehicles and drivers should minimize operating costs subject to constraints imposed by garage capacity, employment standards and agreements, and other relevant factors peculiar to the area served by the system. Each run in the schedule requires a vehicle and a driver in the right place at the right time. Thus, the (often sequential) decisions to be made at this level are

1. *Vehicle Scheduling.* The arrival and departure times of each run at each terminal are drawn from the route schedules discussed in the previous section. These are used to define the number of vehicles of each type to be assigned to each terminal and the set of runs (called a *block*) to be assigned to each vehicle such that all runs can be carried out as scheduled. In formal terms, the fleet of vehicles $F_{v,k}$ of type v assigned to terminal k must satisfy the following relationship [11]:

$$F_{v,k} \geq \max_t \{D_{v,k}(t) - A_{v,k}(t)\}, \quad (2)$$

where $D_{v,k}(t)$ is the cumulative number of departures of type v vehicles from terminal k at instant t , and $A_{v,k}(t)$ is the cumulative number of arrivals of type v vehicles at terminal k at instant t . The sum of these assignments over all terminals and types of vehicles gives the minimum required fleet size for satisfying the entire system schedule. This value can be reduced through modifications to the route schedules such as marginally reducing frequencies, advancing or delaying arrivals, changing assigned vehicle types for a given run, and repositioning vehicles from terminals where more vehicles arrive than the number departing for terminals with a shortage of arrivals. This repositioning usually involves deadhead runs, but where demand exists it may also be traveled with passengers (creating new express services, for example).

The vehicle scheduling process aims at defining vehicle blocks consisting of feasible sequences of runs and repositionings (deadhead vehicle trips) for each vehicle between route terminals or terminals and the vehicle garage. The objective is to minimize a combination of required fleet size and non-revenue time subject to satisfying all scheduled runs. This problem of assigning vehicles to runs starting from a single depot is called the *single depot vehicle scheduling problem* (SDVSP). The SDVSP can be solved in polynomial time. For a detailed overview of the literature on the SDVSP, see Desrosiers [12].

2. *Driver Shift Scheduling.* Once a block has been assigned to each vehicle, they are initially divided into tasks that must be worked by a single driver. So *tasks* start and end at relief points of the network, where vehicles can exchange drivers. The problem of assigning drivers to tasks is called the *crew scheduling problem* (CSP). A CSP is solved for each day of the planning horizon. In the CSP, a minimum cost set of *duties* (sequence of tasks by a

single driver) must be determined so that all tasks are assigned to a duty and each duty can be performed by a driver. The possibility of drivers doing overtime at a higher salary is usually considered in a CSP. Driver constraints like maximum working time without a break, minimum break duration, and maximum working time are typically added. Although CSP looks similar to the SDVSP in structure, it is much more complicated. The CSP has been shown to be NP-hard. Wren and Rousseau [13] present an overview of different approaches for this problem.

Once the driver duties over the planning horizon have been determined, duties are assigned to specific drivers. At this stage, called the *rostering process*, other constraints like rest periods, holidays, training, and so on, are considered. A survey on different approaches for this problem can be found in Odoni *et al.* [14].

This sequential approach for transit systems is inherited from the airline industry, where vehicles are optimized before drivers (crews in this case) since vehicle-related costs have a bigger impact on the total budget. In the case of transit systems based on buses, driver-related costs may be the most significant. Therefore, transit systems may benefit from optimizing drivers first and should do it taking full advantage of driver's flexibility.

This sequential approach to design a transportation system has other important limitations. Performance improvements could be obtained if the problem was solved simultaneously instead, but the complexity of the problem makes it a challenge.

Another drawback of the sequential approach is that it assumes a deterministic system. However, uncertainties are present at all operation levels (e.g., driver absenteeism, passenger demand, roundtrip durations, and vehicle failure) and should be considered in these decisions (e.g., hiring extra drivers, called *extra-board*, may allow operation

in case of absenteeism). Also, an effective control reaction to these and other uncertainties should be designed, as is explained in the next section.

REAL-TIME CONTROL

In the absence of any control system, the vagaries of traffic and of passenger demand at the various stops along a route tend to result in the formation of convoys of road transit vehicles. This phenomenon, known as *bus bunching* [15], has negative effects on the functioning of the transit system. One of these is the impact on average system wait times and their variability. Formally, average wait time $E[W]$ assuming users arrive randomly at a stop is given by

$$E[W] = \frac{E[H]}{2} + \frac{\text{Var}[H]}{2E[H]}, \quad (3)$$

where $E[H]$ and $\text{Var}[H]$ are, respectively, the mean and variance of vehicle headways. Bunching is thus highly undesirable, because it generates a noticeable rise in the variance of the intervals separating successive vehicle runs, which translates into average wait times that are longer and more variable. It also leads to underutilization of vehicle capacity since most passengers will be concentrated on the first vehicle in the bunch. This means that the average user will not only wait longer but also be riding on a fuller vehicle. Moreover, in high-demand scenarios vehicle load capacity is often exceeded and waiting passengers are unable to board the first arriving vehicle. These bunching phenomena impact strongly on perceived service levels, especially since, as mentioned, waiting time has the highest subjective value of all travel time components.

To avoid bunching, various control strategies may be adopted for regularizing headways. These include (i) holding vehicles at stops to prevent them catching up to the vehicle ahead; (ii) skipping stops at which no passenger wants to alight in order to make up time; and (iii) installing a traffic signal priority (TSP) system that can speed up or hold back vehicles.

Other eventualities, such as vehicle breakdowns, closed streets, and so on, may arise. The appropriate actions to be taken in these and other cases should be set out in contingency plans defining how vehicles and personnel are to be reassigned in each type of situation.

CONCLUDING REMARKS

Although the division of decision making into four levels is useful in ordering and ranking the various transit scheduling problems, it must be kept in mind that the design decisions at the strategic level are dependent on the solutions found for the lower level decision problems because of their impact on cost indicators. To solve the strategic design questions, estimates are required of such factors as how many drivers are needed per vehicle, how frequent service on a given route should be, and how long will waiting times be at that frequency, and so on. One of the ongoing challenges for researchers in this area is to develop methodologies that enable these problems at different levels to be solved simultaneously.

For each of the decision levels, we have described a sequence of problems that must be addressed. Each of these problems is complex in and of itself and generally involves not just technical challenges but social, psychological, economic, political, and urban design aspects as well. The presence of these other issues indicates that although operations research, with its techniques based on various types of mathematical modeling (optimization, control, econometric, etc.), is a highly valuable tool, it must be complemented by other decision-making mechanisms.

For an advanced coverage on the mathematical models and solution methodologies of the different problems covered in this article, the reader is referred to Desaulniers and Hickman [9] and Ceder [3].

Planning and operational processes related to railway systems are generally highly complex and are therefore fields that are rich in interesting *operations research* (OR) problems. Railway transportation can be split into passenger and cargo transportation. This article mainly focuses on the planning processes of passenger railway transportation systems.

Currently, in many countries, new regulations specify that the *management* of the railway infrastructure should be separated from its *exploitation*. This introduces, on the other hand, the organization of the *Infrastructure Manager* (IM), who is responsible for expansion and maintenance of the railway infrastructure as well as for capacity allocation and real-time traffic control, and, on the other hand, the *Train Operators* (TOs). The TOs provide passenger and cargo rail services by developing their preferred timetable, and by operating their rolling stock and crews. They usually operate on a commercial basis. In cooperation with the TOs, the IM integrates the preferred timetables of the TOs into one published timetable.

Simulation has always been recognized by the railway industry to be a fundamental OR tool for the planning phase, to be applied

extensively before putting any new timetable into operation in order to hopefully highlight its main strengths and weaknesses. The main advantage of simulation is that it allows the user to consider very detailed models of reality, and that it is fairly easy to adapt the associated software to refine/update these models. On the other hand, simulation is aimed at *evaluating* only possible solutions to the planning problems to be faced, whereas the number of these solutions is huge due to their intrinsic combinatorial structure. For example, if there are 12 trains in a short time period on a certain route, then the number of possible cyclic orders of trains after another on this route equals already $11! = 39916800$. Furthermore, considering all routes in the railway network at the same time increases the number of possible solutions in an exponential way.

Until recently, the possible solutions that were tested through simulation and eventually put into operation were generally designed by human experts: although this approach may lead in the end to solutions that are acceptable in practice, the time to generate such solutions in this way is unavoidably long. This is undesirable in an environment that, due to competition, is increasingly aiming at service and efficiency. Moreover, it gives almost no room for systematic what-if analyses of different scenarios (e.g., what would change by increasing the minimum time between two consecutive train trips to be assigned to the same driver?). For these reasons, in the last years, we have witnessed an increasing interest toward the application of mathematical models and optimization techniques for solving railway planning problems.

This trend is facilitated by fast developments in computer hardware and algorithmic power. Furthermore, it also follows the example of the airline industry, where these techniques were introduced already some time ago in order to cope with privatization and competition. There are many similarities between railway and

Figure 1. Illustration of the main problems solved in the planning of a passenger railway system.

airline systems. For example, both operate based on a timetable by allocating vehicles (airplanes vs trains) that are staffed by certain crews (cockpit and cabin crew versus train drivers and conductors). However, there are also differences. For example, an airline system usually has a much better insight into the numbers and destinations of the passengers than a railway system, since seat reservation is customary for airlines but often not for railways. Furthermore, in a railway system the infrastructure may be much more restrictive than in an airline system, and an airplane consists of a single vehicle whose type determines its capacity, whereas the capacity of a train can be adapted by coupling additional carriages or train units.

In this work, we focus attention on the various optimization problems that are faced in the planning and real-time operations of a passenger railway system, from the definition of the routes and frequencies of the trains in the railway network to the assignment of the workload to be carried out by the drivers and conductors, presenting them in the sequence in which they are faced in practice. We start with line planning, which amounts to deciding the routes for the trains as well as the types and frequencies of the trains on each route. Next, the actual timetable of each train has to be fixed by train timetabling and by assigning the trains to routes and platforms in the stations they visit. The assignment of rolling stock (locomotives and train carriages or train units) to the trains with a

known timetable is specified by the rolling stock planning. Finally, the assignment of the workload of drivers and conductors to operate the trains in a given timetable is the purpose of crew planning. This is illustrated in Fig. 1, which depicts the list of problems along with their input/output.

Surveys on optimization problems arising in passenger rail transportation systems can be found in Bussieck *et al.* [1], Caprara *et al.* [2], and Huisman *et al.* [3], to which the reader is referred for further details and references.

We conclude this introduction by noting that we will not discuss fundamental problems in strategic planning, related to deciding on the resources that are required to accomplish the passengers' demand, such as the capacities of the infrastructure, the rolling stock, and the crews. Although an enormous amount of money is involved with the management of these resources, the related strategic decisions are currently usually still taken without OR tools.

Additional passenger transportation problems are discussed in the articles titled *Air Traffic Management*, *Airline Resource Scheduling*, *Traffic Network Analysis and Design*, *Travel Demand Modeling*, and *Optimization of Public Transportation Systems* in this encyclopedia, whereas issues on rail cargo transportation and logistics are discussed in the article titled *Operations Research Applications in Truckload Freight Transportation Networks* in this encyclopedia.

Solution Methods

The simplest practical approach to solve the problems illustrated here is the use of various types of constructive and local search (meta-)heuristics, which often simulate what a human expert is doing to construct a solution manually. One clear drawback of these approaches is that they provide neither lower nor upper bounds to guarantee the quality of the solutions found. Moreover, this quality can often be improved by using mathematical programming tools.

For most problems considered here, as well as for most other optimization problems that are solved in practice (to the best of our knowledge), the mathematical programming methods that are used successfully are based on stating the problem as a *mixed-integer linear program* (MILP), often after having represented it on a suitable graph. These MILPs are solved as they stand (by using a general-purpose solver), or by applying constraint/column generation techniques combined with the solution of reduced *linear programming* (LP) relaxations (again by using a general-purpose solver), or also by applying methods to approximately solve (reduced) LP relaxations such as Lagrangian relaxation. The use of MILPs to model real-world problems and their practical solution is discussed in the articles titled **Formulating Good MILP Models**, **Branch-and-Bound Algorithms**, **Branch and Cut**, and **Branch-Price-and-Cut Algorithms** in this encyclopedia. In addition, constraint programming and its combination with MILP techniques appears to be of particular interest for railway timetabling [4].

THE MAIN PROBLEMS

In this section, for space reasons, we do not present the main MILP formulations of the problems explicitly, but we limit ourselves to mention their decision variables, along with the possible use of graphs to derive these formulations. Moreover, for each problem, we give some references where more details on mathematical models, exact and heuristic algorithms, and computational results on real-world instances can be found. Several

additional references are listed in the three surveys [1–3] mentioned above.

Line Planning

Most passenger TOs operate a timetable in which the scheduled trains can be partitioned into a number of so-called *lines*, containing trains with the same route and the same set of stop stations. The only difference between the trains of each line is the arrival and departure times. The *frequency* of a line denotes the number of trains that run in each direction per time unit (e.g., hour or day) on their common route, whereas its *capacity* is the overall number of seats provided by the trains on the line. In a *cyclic* line system, the difference of the departure times of the trains in the same direction is always about one (submultiple of the) cycle time.

The *line planning problem* (LPP) is the problem of designing a line system such that the *passengers' demand* is satisfied. There are two main conflicting objectives, namely, (i) maximizing the service toward the passengers and (ii) minimizing the operational costs of the railway system. According to (i), *direct passengers* are the passengers who can travel from their origin station to their destination station without having to change trains. Maximizing the number of direct passengers usually results in long lines: the longer a line, the more direct connections are provided. However, long lines may transfer delays more easily over a wider geographical area, and they may prohibit an efficient allocation of rolling stock.

LPP requires to define, for each possible line, whether to use it at all (i.e., to have trains running accordingly) and in this case with which frequency and capacity. The objective is to minimize the weighted sum of the connection costs for the passengers and the operating costs for the TO, subject to the constraint of satisfying the passengers' demand.

Note that if the line system is assumed to be symmetric (i.e., each line is operated in both directions with the same frequency), and all trains on a line have the same capacity, then it may be assumed without loss of generality that the origin/destination matrix is symmetric. However, if the

origin/destination matrix is strongly non-symmetric, for example, during rush hours, then it may be useful to allow the line system to be nonsymmetric as well.

A basic version of LPP assumes that the passengers have been already routed through the network before the optimization, for example, based on the assumption that they use shortest paths and intercity services as much as possible. On the basis of this system split assumption, LPP decomposes into two subproblems, concerning, respectively, intercity lines and regional lines. An advantage of this decomposition is that, within each subproblem, the stations may be considered as having the same type.

This basic version of LPP is naturally formulated by representing the railway network as an undirected graph $G = (V, E)$, with a node in V for each station and an edge in E for each track joining two stations. Moreover, assume that the passengers' demand is given by the matrix $d_{(i,j)}$, representing the number of passengers who want to travel from node i to node j . Then an initial MILP formulation is obtained by listing explicitly all possible lines with their frequencies and capacities, say l, f, c , and then by introducing binary variables $x_{l,f,c}$, which are equal to 1 if line l with frequency f and capacity c is activated, and "continuous" variables $y_{l,(i,j)}$ expressing the number of direct passengers between nodes i and j along line l . Details of this basic model can be found in Goossens *et al.* [5].

In extended versions of LPP, the passengers also have to be routed through the network. In this case, the intercity lines and the regional lines must be considered simultaneously. This approach clearly assumes that there is some "authority" that guides the passengers through the railway network from their origin to their destination. Furthermore, one may avoid considering the whole set of lines explicitly, using dynamic column generation to generate them. Details of these extended approaches can be found in Borndörfer *et al.* [6].

Train Timetabling

The general aim of the *train timetabling problem* (TTP) is to provide a timetable for the

trains of the TOs on a certain part of the railway network. For both cyclic and non-cyclic timetables, the problem for the general case of many TOs and a unique IM can be formalized schematically as follows. Each TO generates his/her own *ideal timetable* and submits this to the IM. Then the IM, in cooperation with the TOs, integrates the ideal timetables of the TOs into one single timetable. Thus, there are two stages of TTP. In the first stage, the ideal timetables of the individual TOs have to be generated. In the second stage, the ideal timetables of the TOs have to be integrated into a single timetable.

Relevant aspects to be taken into account in TTP are running times and dwell times of single trains, and headway and connection times between pairs of trains. Relevant objectives to be pursued in the first stage of TTP are to minimize the travel times of the passengers or to maximize the efficiency or the robustness of the timetable. In the second stage, the ideal timetables of the TOs are integrated into one single timetable. Here, the input consists of the ideal timetables of the TOs, along with a *fee* the TO is willing to pay to the IM for each of his/her trains and the *penalties* to be paid by the IM for possible deviations of the integrated timetable from the ideal timetables. Now the TTP is the problem of determining, for each train, whether to schedule it or not, and, in the former case, its *actual timetable*. The objective is to maximize the difference between the global fee of the trains scheduled and the global penalty for the deviations from the actual timetables with respect to the ideal ones. These deviations are required to satisfy the operational constraints that impose, for safety reasons, a minimum headway time between trains traveling on the same section of the infrastructure.

There are two main MILP formulations that are used both for the first and second stage of the TTP. The first formulation can be used to generate a cyclic or a noncyclic timetable. This MILP formulation discretizes the time horizon; for example, for a time horizon of one day, it assumes that all times are expressed by an integer number of time units (e.g., minutes). In the cyclic case, all departure and arrival times are

expressed modulo (a submultiple of) the cycle time. Then the problem is represented in a directed space–time graph whose nodes represent departure or arrival of trains at stations along specific tracks. The arcs of this graph represent either a train traveling between two adjacent stations (in case they join a departure node to an arrival node), or a train stopping at a station (in case they join an arrival node to a departure node). The timetable for a single train corresponds to a path in this graph. The natural MILP formulation has binary variables $x_{t,a}$ equal to 1 if the path for train t uses arc a . Details can be found in Caprara *et al.* [7].

The other MILP formulation is based on the periodic event scheduling problem (PESP), which was introduced by Serafini and Ukovich [8]. PESP focuses on the generation of a cyclic timetable with cycle time T . The MILP model has “continuous” variables $x_{t,e}$ expressing the time in the interval $[0, T - 1]$ at which the *event* e , corresponding to a departure/arrival at a station, occurs for train t . Furthermore, each constraint imposes that the difference between two variables $x_{t,e}$ and $x_{u,f}$ must be between a given lower bound and a given upper bound (modulo the cycle time T). All constraints can be represented in a so-called *constraint graph*. The modulo operation is linearized by introducing binary variables, whose “big M ” coefficient equals the cycle time. An alternative formulation of PESP does not use decision variables for the event times, but for the process times. Here one has to satisfy the additional constraint that the sum of the process times along any directed cycle in the constraint graph is a multiple of the cycle time T . Details can be found in Liebchen [9].

Train Platforming

The definition of the actual timetables within TTP generally does not take into account the actual routing of the trains within the stations. This is the purpose of the *train platforming problem* (TPP), which must be solved separately for each station, in which one has to find for each train a so-called *route* from the point where it enters the station to the point where it leaves the station, taking into account that the times in which these two

events occur have already been specified by TTP.

Assuming for simplicity that each train has to stop at a platform, a route is specified by the platform itself plus arrival/departure routes joining its entry/exit points to the platform. Several objectives are generally taken into account, such as the minimization of the number of platforms used and the penalties incurred if a train is not assigned to a platform within a given preference list. Also a maximal robustness of the platform assignment may be pursued, since the stations are often considered as the bottlenecks in the railway system. Operational constraints impose a minimum time interval between the departure of a train and the arrival of the next train at a platform, and forbid the simultaneous occupation of an incompatible pair of routes (generally physically crossing in the station layout) by two trains.

The commonly used MILP formulation of TPP considers explicitly the full list of routes for each train (which is generally acceptably long), and uses binary variables $x_{t,r}$ equal to 1 if train t is assigned to route r , plus possibly binary variables y_p equal to 1 if platform p is used by at least one train. Details can be found in Zwaneveld *et al.* [10] and Caprara *et al.* [11]. Recently Caimi [12] presented an approach focusing on the railway infrastructure: it guarantees that each section of the infrastructure is claimed by at most one train at the same time, which leads to a stronger LP relaxation.

Rolling Stock Planning

The rolling stock to be assigned to the trains whose timetable has been found by TTP can either be locomotives and train carriages, or aggregated modules, subsequently called *train units*. The latter are composed of a number of carriages in a fixed composition, and can move in both the directions without the need of an extra locomotive. A train can then be composed of several coupled train units. Train units may exist in different types, representing technical characteristics and capacity. For simplicity, we restrict our attention to the train unit case.

In order to obtain a better match between the available rolling stock and the passengers' seat demand, the compositions of the trains usually can be changed at several stations by adding or removing rolling stock from the trains. We let a *trip* to be a part of a train timetable that must be performed by the same rolling stock without changes. The *rolling stock planning problem* (RSPP) calls for assigning (combinations of) train units to trips.

The nature of the railway network plays a major role in the problem, in particular, in relation to the maintenance needs of the train units. Namely, in a sparse network with long distances, and hence long travel times and relatively low frequencies of trains, RSPP must specify in detail the circulations of the individual train units over the planning horizon, thereby taking into account the fact that each individual train unit should reach a maintenance center sufficiently often. In contrast, in a dense network with relatively short distances and high frequencies of trains, the train unit circulation is usually anonymous but contains sufficient time reservations for maintenance. Maintenance can be planned then just before the actual operations by exchanging duties of train units based on the assumption that all train units of the same type that do *not* need maintenance at that time are interchangeable.

In all cases, RSPP requires the minimization of a weighted sum of the costs of the total distance traveled by train units, of the composition change costs, and of the seat shortages with respect to the expected passengers' demand, subject to the train unit availability. Operational constraints impose a maximum length for each train (based on the shortest platform along which the train will dwell), besides requiring that composition changes can be done by respecting the timetable and that maintenance is carried out properly in the sparse network case.

A natural representation of RSPP is based on a directed multigraph $G = (V, A)$ with a node in V for each trip. The arc set A is partitioned into different sets A^t , one for each train unit type t . An arc $(i, j) \in A^t$ represents the fact that trip j can appear right after trip i in a feasible sequence for train unit type t . With

this representation, RSPP can be modeled as a multicommodity flow problem. Namely, it calls for a min-cost collection of *paths* of G , each associated with arcs of the same type, such that each node is visited by a sufficient number of paths, with several constraints on the path feasibility. This can either be modeled by using integer variables $x_{(i,j)}^t$ equal to the number of times arc $(i, j) \in A^t$ is in a path in the solution, or by considering the whole list $\mathcal{P}^t$ of paths for train unit type t and integer variables x_P equal to the number of paths $P \in \mathcal{P}^t$ in the solution. In this case, dynamic column generation is a useful approach due to the large number of potential paths. Details can be found in Cordeau *et al.* [13] and Cacchiani *et al.* [14]. Fioole *et al.* [15] use the concept of *transition graphs* to restrict the possible changes in the compositions of the trains in the stations.

Planning the shunting processes related to train units that are temporarily idle at a station, involving, for example, matching of arriving and departing train units, routing them through the station, and parking them in appropriate shunting tracks, is also an important part of RSPP. Several aspects of these problems have been modeled as MILPs [16].

Crew Planning

The *crew planning problem* (CPP) is the counterpart of RSPP involving crews (train drivers and conductors). It is concerned with covering each trip in the timetable with the required number of crews. That is, at least one driver and a sufficient number of conductors must be assigned to each trip. Here, a *trip* is a part of a train timetable that must be performed by the same crew without changes. Generally these trips are shorter than the trips for the rolling stock since a crew change requires less time. CPP represents a very complex and challenging problem, due to both the size of the instances to be solved and the type and number of operational constraints. It is usually decomposed into the following two phases.

In the *crew scheduling* phase, the short-term schedule of the crews is considered, and a convenient set of *duties* (also called *pairings*) covering all the trips is constructed.

Each duty represents a sequence of trips to be covered by a single crew member within a short time period overlapping at most one or two consecutive days. In the *crew rostering* phase, the duties selected in the crew scheduling phase are sequenced to obtain the final rosters, which describe for each crew member the sequence of duties to be carried out on consecutive days. Here, trips are no longer taken into account explicitly, but determine the *attributes* of the duties which are relevant for the roster feasibility and cost.

The main objective of CPP is the minimization of the global number of crews needed to perform all the daily occurrences of the trips in the given planning horizon. In some applications, for example when the considered trains cover a relatively small area and run mainly within the daytime, the crew rostering phase plays a minor role, since the corresponding constraints are rather weak and the number of crews is easily determined from the solution of the crew scheduling phase. In this case, the objective used in the crew scheduling phase mainly calls for the minimization of the number of working days corresponding to the duties. In applications involving several trains covering a wide area and/or running overnight, instead, considerable savings can be obtained through a clever sequencing of the duties obtained in the first phase. Therefore, the objective of the crew scheduling phase has to take into account the characteristics of the duties selected and their implication in the subsequent crew rostering phase.

Both crew scheduling and rostering phases in CPP, as well as RSPP, require finding min-cost *sequences* through a given set of *items*. Items correspond to trips for crew scheduling and for RSPP and to duties for crew rostering, whereas sequences correspond to duties for crew scheduling and to rosters for crew rostering. A natural representation is on the same graph considered for RSPP, and the MILP models are analogous, with the difference that often there is a unique crew type and it is sufficient to assign one crew to each item. Details can be found in Caprara *et al.* [17] and Kroon *et al.* [4]. For solving such problems of practical size, dynamic column generation

is usually necessary due to the huge number of potential sequences of items, and to the complex rules that must be satisfied by these sequences, in particular in the case of CPP.

ROBUSTNESS ISSUES

As mentioned in the introduction, simulation is often used to validate the solutions of the problems mentioned before, and it points out their strengths and weaknesses with respect to *disturbances*. These are external events in the real-time operations that were not taken into account in the optimization of the plans. An example of a disturbance is the extended duration of a dwell time due to an unexpectedly large number of alighting and boarding passengers.

Recently, considerable efforts have been made to take into account disturbances already in the optimization phase, although unavoidably with models of reality that are less accurate than in simulation. Roughly speaking, the general idea of robustness is to optimize a weighted combination of the original objective function and a penalty due to the operational costs in case of disturbances (taking into account an estimate of the probability of the occurrence of these disturbances). These methods are discussed in a general setting in the articles titled ***Two-Stage Stochastic Integer Programming: A Brief Introduction, Dynamic Models for Robust Optimization, Introduction to Robust Optimization*** in this encyclopedia.

The first, and most natural, approach to introduce robustness is *stochastic programming*, in which, besides the *nominal* scenario corresponding to the absence of disturbances, an explicit list of the other possible scenarios must be given along with the associated probability. The resulting mathematical programming models have a subproblem for each scenario, their size growing therefore linearly in the number of scenarios. This forces the number of scenarios to be small in practical applications. Later, other approaches to deal with robustness that are less cumbersome than stochastic programming (and allow one to implicitly consider infinitely many scenarios) have been proposed.

The approaches in Soyster [18], Ben-Tal and Nemirovski [19], and Bertsimas and Sim [20] keep the original (nominal) objective function and guarantee that the solution is feasible not only for the nominal scenario but also for all other scenarios. They implicitly list these scenarios as a mathematical program, through uncertainties in the data defining the problem constraints. (For example, in Bertsimas and Sim [20], each entry of the constraint matrix can vary within given intervals and at most a given number of entries of the same row can vary at the same time.) These approaches have the clear disadvantage that they focus on finding a solution that is feasible for all scenarios, which may not even exist at all, and in any case may be of very bad quality.

This is relaxed in the *light robustness* approach of Fischetti and Monaci [21], which, starting from the formulation in Bertsimas and Sim [20], includes a new objective function taking into account the amount of constraint violation for all scenarios and a new constraint stating that the value of the original objective function should not deviate too much from the optimal nominal value.

In any case, the main drawback of all the methods in the above paragraph is that, unlike stochastic optimization, they do not consider the possibility of changing the nominal solution within the operations to adapt it to the scenario that is occurring in practice. This inspired the notion of *recoverable robustness* [22], which essentially combines the notion of a recoverable algorithm that is used to adapt the nominal solution to the actual scenario and the implicit representation of the list of scenarios as a mathematical program, without any assumption on the probabilities associated with these scenarios.

REAL-TIME CONTROL

Real-time control aims at monitoring the real-time system and at restoring the system once one or more events occurred that made the original plan infeasible or that will make it infeasible soon. Such an event may be a relatively small *disturbance*, or a large *disruption*. Real-time control may be carried

out in a reactive way, when the plan has become already infeasible, or in a proactive way, when the plan is going to become infeasible. Therefore, forecasting future states of the system is an important issue in real-time control. Anyway, for real-time control short computation times are extremely important, possibly leading to suboptimal solutions.

In the case of a disturbance, the infeasibility can usually be restored by relatively small measures by traffic control, for example, giving speed advises to trains or rerouting trains inside stations. In these cases, it is often assumed that the changes to the timetable can be conducted without rescheduling rolling stock and crews. D'Ariano *et al.* [23] describe a branch-and-bound procedure that can be used to improve the quality of such timetabling decisions. Their model is based on the disjunctive arc model by Mascis and Pacciarelli [24].

A closely related problem is delay management. This problem is used to find optimal wait-depart decisions for connecting trains when the feeder train is delayed, so that the total passenger delay is minimized. Schöbel [25] describes MILP models for solving the delay management problem. Here, the wait-depart decisions are modeled by binary variables.

A large disruption may be caused, for example, by malfunctioning infrastructure or rolling stock, or by an accident. Such a large disruption may lead to less railway traffic on the involved infrastructure for a certain period of time, or to no railway traffic at all. As a consequence, the timetable, rolling stock circulation, and crew duties must be adapted accordingly. A problem here is that the duration of the disruption is usually not known in advance.

For adapting the structure of the timetable, often disruption scenarios are used, in particular, in the case of a cyclic timetable. However, recovering the rolling stock circulation and the crew duties may be more complicated. Nielsen *et al.* [26] describe an adapted version of the rolling stock planning model of Fioole *et al.* [15] for this purpose. In order to keep their running times low, the model is applied on a rolling horizon.

Rezanova and Ryan [27] and Potthoff *et al.* [28] describe an adapted version of a set covering model for rescheduling the crew duties. They keep the running times low by only considering a well-selected subset of the original duties: the duties that probably cannot be helpful for the rescheduling of the disrupted duties are not considered. For both rolling stock and crew rescheduling, it is important to keep intact the parts of the original plans that need not be modified.

FINAL REMARKS

An overview of optimization models for operational railway line planning, train timetabling and platforming, and rolling stock and crew planning has been given. These models are applied more and more in practical planning environments. The next challenge is to apply them also in the dynamic environment of real-time control and disruption management.

OPTIMIZING PASSENGER SCREENING FOR AVIATION SECURITY

Passenger screening at aviation security checkpoints is a critical component in protecting airports, airlines, and passengers from terrorist threats. Historically, terrorist activity has directly influenced the reform of security screening strategies in an effort to adapt to an ever-expanding list of improvised threats. However, the reactive nature of many of these changes, such as the 3-1-1 liquid and gel policy for carry-on baggage, for example, has caused increases in the cost associated with resolving alarms for non-threatening passengers and inconvenience to travelers due to longer screening times.

Passengers are screened prior to entering the airport terminal using a set of security detection devices and procedures, such as magnetometers, explosive detection systems, pat-down searches, and explosive trace detection devices. There are two possible ways to screen passengers for threat items: (i) uniform screening and (ii) risk-based screening. In uniform screening, all passengers are deemed to pose equal

threat to the aviation transportation system, by carrying a concealed threat item within their clothing or baggage. Because of budget constraints surrounding the purchase, maintenance, and operation of the detection devices, it is neither economically nor logistically feasible to screen all passengers at the same level of intensity, especially using specialized devices and procedures that are time-intensive. Furthermore, a random selection policy for assigning passengers to undergo higher screening intensity exhibits the vulnerability to under screening passengers who are indeed a threat.

A risk-based screening strategy addresses this vulnerability by quantifying a perceived risk of each passenger, and assigning this passenger to be screened by an appropriate set of devices. The computer-aided passenger prescreening system (CAPPS), developed by the Federal Aviation Administration, Northwest Airlines, and the United States Department of Justice, is an automated risk assessment system to assess passengers' risk, based on factors such as personal information, prior travel history, and other security-sensitive information [1]. CAPPS designates passengers as either *selectees* (i.e., those not cleared by CAPPS) or *nonselectees* (i.e., those cleared by CAPPS). When capacity permits, non-selectees are randomly chosen to undergo higher screening intensity in an effort to fully utilize the available security resources.

A risk-based screening strategy may also be used to quantify the perceived risk of passengers using a continuous spectrum of assessed threat values (as opposed to two distinct categories in CAPPS), where the passengers are directed to undergo certain levels of screening intensity based on a set of threshold values. This article develops a multiobjective optimization problem, where the goal is to obtain a threshold-based passenger assignment policy that balances the trade-off between maximizing security and minimizing the expected amount of time it takes to screen passengers and baggage through the security checkpoint. Stochastic models

*Affiliated with Vishwamitra Research Institute in 2009–2010.

are used to capture the queueing dynamics of the passengers as they proceed through the security checkpoint. Passengers arrive sequentially at the security checkpoint, and are directed to undergo the appropriate level of screening intensity based on uncertainties surrounding their corresponding perceived risk levels, the passenger arrival times, and the detection device screening times. An optimal policy is obtained for sequentially assigning passengers to a multilevel security system and to a security system comprising primary and secondary levels of screening.

PROBLEM FORMULATION

A multilevel security system within an airport terminal assigns each passenger to one of several available *security classes* according to the perceived risk for this passenger, where the security classes are composed of sets of security detection devices and procedures. Each device and procedure individually specializes in detecting a specific type of threat, such as guns, knives, and explosives, while operating collectively to screen a passenger or bag at a certain level of intensity. The problem of assigning passengers to the appropriate security class is explored dynamically, where the assignment decision must be made as each passenger arrives at the security checkpoint for screening, and without knowledge of future passenger risk.

Let M be the number of security classes available for screening passengers, and let L_m denote the security level of class $m = 1, 2, \dots, M$, with $0 \leq L_1 \leq L_2 \leq \dots \leq L_M \leq 1$. The value L_m is defined as the conditional probability that an alarm occurs for a passenger who is a threat, given that the passenger is assigned to security class m (i.e., the conditional true alarm rate). Because of the procedures and technologies associated with each screening device, the rates at which passengers are screened vary across the security classes. Assume that due to these sets of screening devices, the security class service rates are exponential, with rates $\mu_1 > \mu_2 > \dots > \mu_M > 0$, where passengers are screened faster (slower) through security classes of lower (higher) levels of intensity

using a set of routine (specialized) devices and procedures. Also, assume that passengers arrive independently and sequentially at the security checkpoint according to a Poisson process with rate $\lambda > 0$. For stability, assume $\lambda < \sum_{m=1,2,\dots,M} \mu_m$ (i.e., collectively, the multilevel security system is capable of screening passengers at a rate faster than the arrival rate).

Passengers sequentially arrive at the security checkpoint for screening, indexed as $i = 1, 2, \dots$ upon arrival at times $t_1, t_2, \dots$. Upon check-in, the perceived risk for each passenger is quantified by security personnel into an *assessed threat value*, scaled between zero and one, captured through the independently and identically distributed random variables $AT_1, AT_2, \dots$, with realizations $\alpha_1, \alpha_2, \dots$. The cumulative distribution function $F_{AT}(\alpha_i), i = 1, 2, \dots$ is defined over $[0, 1]$. The value of α_i quantifies a risk perception for use in a risk-based security system, where passengers may be screened at various degrees of intensity. Since security personnel cannot know if a passenger is indeed a threat, the assessed threat value reflects their perception of the probability of that passenger being a threat. The value α_i corresponds to the probability that passenger i is a threat, where a value of α_i close to one (zero) corresponds to a high-risk (low-risk) passenger. A passenger cannot be identified as a threat until a security detection device signals an alarm and the alarm is confirmed to be positive. The value α_i is assigned to passenger i upon check-in, either at the ticket counter or on-line, but is considered unknown to the security personnel located at the terminal checkpoint, since the order of passengers might change from check-in to screening. Also, this allows the assessed threat value to be altered based on other screening techniques, such as behavior detection officers, prior to the passenger entering the screening process. Thus, the assessed threat value becomes available for assigning the appropriate level of screening once the passenger first enters the screening process, reflected through the realization of the random variable AT_i .

The decision to assign passenger i to security class m in a multilevel security system is

a function of the passenger's assessed threat value in relation to a set of *security class threshold values*, $b_m(t), m = 1, 2, \dots, M, t \geq 0$. The value $b_m(t)$ determines the upper threshold value for security class m , where $0 < b_1(t) \leq b_2(t) \leq \dots \leq b_M(t) \equiv 1$ partition the interval $(0, 1]$ into M subintervals. The security class assignment for passenger i is represented by the Bernoulli random variable, $X_m(t_i) = 1$ (0) if passenger i is (not) assigned to class m , with observed value, $x_m(t_i)$. Define $p_m(t_i) = P(X_m(t_i) = 1), m = 1, 2, \dots, M, i = 1, 2, \dots$, as the probability that passenger i entering screening at time $t = t_i$ is assigned to security class m . The objective is to determine the values $b_m(t_i), m = 1, 2, \dots, M$ that assigns passenger i to the appropriate security class, subject to capacity constraints. With $p_m(t_i) = P(X_m(t_i) = 1) = P(b_{m-1}(t_i) < AT_i \leq b_m(t_i)), m = 1, 2, \dots, M, i = 1, 2, \dots$, the values $b_m(t_i)$ are related to $p_m(t_i)$ through $b_m(t_i) = F^{-1}_{AT} \left(\sum_{k=1,2,\dots,m} p_k(t_i) \right), m = 1, 2, \dots, M$. Therefore, obtaining the optimal security class assignment probabilities $p_m(t_i)$ for each passenger arriving sequentially at the security checkpoint is equivalent to obtaining the optimal security class threshold values $b_m(t_i)$, which assign each passenger to undergo the appropriate level of screening.

PASSENGER ASSIGNMENT POLICY

First, consider a passenger assignment policy in which each passenger is assigned to a security class independent of all prior passenger assignments. This implies that the assignment decision operates independent of the number of passengers currently in the security system, and sequentially assigns the passengers according to some predetermined set of constant security class threshold values. This type of policy can be applied, for example, to the random selection of nonselectee passengers for higher intensity screening, in an effort to completely utilize the set of devices used specifically for screening selectee passengers.

A *steady-state* queueing analysis is used to provide an expression for the steady-state expected amount of time a passenger spends

in a security system, $E[W]$. The passenger screening process is modeled as a multilevel, single-server exponential queueing system with infinite capacity (see also the section titled "Queueing Theory and Queueing Networks" in this encyclopedia). The objective of minimizing the steady-state amount of time each passenger spends in the security system can be solved through the following nonlinear program (NLP) for a set of constant values $p_m, m = 1, 2, \dots, M$ (see also the section titled "Nonlinear Programming and Global Optimization" in this encyclopedia)

$$\begin{aligned} \text{minimize } E[W] &= \sum_{m=1}^M p_m / (\mu_m - \lambda p_m) \\ \text{subject to } 0 &\leq p_m \leq 1, m = 1, 2, \dots, M, \\ p_m &< \mu_m / \lambda, m = 1, 2, \dots, M, \\ \sum_{m=1}^M p_m &= 1. \end{aligned} \quad (1)$$

The second (strict) inequality constraint, $p_m < \mu_m / \lambda$, corresponds to the stability condition, and, in practice, can be replaced with $p_m + \varepsilon_m \leq \mu_m / \lambda$, for some $\varepsilon_m > 0$. The minimum values of $p_m, m = 1, 2, \dots, M$ are obtained by taking the limit as $\varepsilon_m \rightarrow 0$. For a two-class system, the minimum solution to the NLP in Equation (1) can be obtained by substituting the relation $p_2 = 1 - p_1$ and differentiating to solve for the optimal value p_1^* . Note that, if the security class service rates are identical, $\mu_1 = \mu_2 = \dots = \mu_M$, then $p_1^* = p_2^* = \dots = p_M^* = 1/M$.

Alternatively, a *transient* queueing analysis allows the queue length to be used as feedback into a dynamic passenger assignment process to balance the expected amount of time a passenger spends in the security system with the expected number of true alarms. Let the discrete random variable TA_i be defined as the number of *true alarms* (i.e., correctly detecting a threat item) over the first i passengers to enter screening. Then,

$$E[TA_i] = \sum_{\tau=1}^i \sum_{m=1}^M L_m p_m(t_\tau) \alpha_\tau \quad (2)$$

is the expected number of true alarms in the security system over the first i passengers. Let the continuous random variable $W(t_i)$ be defined as the amount of time passenger i spends in the security system. The optimal assignment policy that determines the sequence of security class threshold values $\{b_m(t_i), i = 1, 2, \dots, m = 1, 2, \dots, M\}$ is the policy which minimizes $E[W(t_i)]$ and maximizes $E[TA_i]$ for each passenger assignment. Clearly, if minimizing $E[W(t_i)]$ is not an issue, then the policy that maximizes $E[TA_i]$ is simply to have all passengers undergo maximum screening (i.e., $p_M(t_i) = 1, i = 1, 2, \dots$). However, by defining a dual objective, a balance must be achieved between security and passenger throughput.

To analyze the passenger screening process, the airport security checkpoint is modeled as a multilevel, single-server exponential queueing system, where each security class has finite capacity $c_m, m = 1, 2, \dots, M$. The number of passengers in security class m at time t_i , denoted by the discrete random variable $S_m(t_i)$, is formulated as a discrete-time, nonhomogeneous Markov chain, with transition probabilities $P_m^{kj}(t_i), m = 1, 2, \dots, M, i = 1, 2, \dots$ (see also the section titled “Discrete-Time Markov Chains” in this encyclopedia). Let the continuous random variable $W_m(t_i)$ be defined as the amount of time passenger i spends in security class m . A recursion for $E[W_m(t_i)]$ is obtained as

$$\begin{aligned} E[W_m(t_{i+1})] \\ = E[W_m(t_i)] + p_m(t_i)(1 - P(N_m^s(t_i, t_{i+1}) = 0, \\ S_m(t_i) = c_m))/\mu_m - E[N_m^s(t_i, t_{i+1})]/\mu_m, \end{aligned} \quad (3)$$

$m = 1, 2, \dots, M, i = 1, 2, \dots$, with $E[W_m(t_1)] = 1/\mu_m$, and where $N_m^s(t_i, t_{i+1})$ is the discrete random variable corresponding to the number of passengers screened in class m during the time interval $(t_i, t_{i+1}]$. From Equation (3), the expected amount of time passenger i spends in the security system, $E[W(t_i)]$, can

be obtained from

$$\begin{aligned} E[W(t_i)] &= \sum_{m=1}^M p_m(t_i) E[W_m(t_i)], \\ m &= 1, 2, \dots, M, i = 1, 2, \dots \end{aligned} \quad (4)$$

The dual objectives of minimizing the expected amount of time each passenger spends in the security system and maximizing the expected number of true alarms can be combined into a single weighted objective function by normalizing each objective term, and introducing cost weight parameter η_1 . The mean square cost associated with the true alarm probability results from the difference between assigning passenger i to class m and assigning passenger i to class M (i.e., the highest level of screening intensity) is defined by

$$\begin{aligned} C^Z(t_i) &\equiv \left[1 - \sum_{m=1}^M p_m(t_i)(L_m - L_1)/(L_M - L_1) \right]^2, \\ i &= 1, 2, \dots, \end{aligned} \quad (5)$$

such that $0 \leq C^Z(t_i) \leq 1$. Next, the mean square cost associated with the expected amount of time passenger i spends in the security system is defined by

$$\begin{aligned} C^W(t_i) &\equiv \left[\left(\sum_{m=1}^M p_m(t_i) E[W_m(t_i)] - w_{\min} \right) \right. \\ &\quad \left. / (w_{\max} - w_{\min}) \right]^2, i = 1, 2, \dots, \end{aligned} \quad (6)$$

where $w_{\max} = \max_{m=1,2,\dots,M} \{E[W_m(t_i)]\}$ and $w_{\min} = \min_{m=1,2,\dots,M} \{E[W_m(t_i)]\}$ such that $0 \leq C^W(t_i) \leq 1$.

The policy that minimizes the cost-weighted dual objective can be obtained by solving the following NLP for $p_m(t_i), m = 1, 2, \dots, M$, for each successive passenger $i = 1, 2, \dots$ arriving at the security checkpoint:

$$\begin{aligned} &\text{minimize } (1 - \eta_1)C^Z(t_i) + \eta_1 C^W(t_i) \\ &\text{subject to } 0 \leq p_m(t_i) \leq 1, m = 1, 2, \dots, M, \\ &\quad \sum_{m=1}^M p_m(t_i) = 1. \end{aligned} \quad (7)$$

The scalar weight $0 \leq \eta_1 \leq 1$ is used to create a cost trade-off between security versus passenger throughput. The value $\eta_1 = 0$ places full emphasis on security, by assigning all passengers to undergo the highest level of screening intensity, while the value $\eta_1 = 1$ places full emphasis on expediting screening, by assigning each successive passenger into the security class with minimal expected amount of system time. For a two-class system, the minimum solution to the NLP in Equation (8) can be obtained by substituting the relation $p_2(t_i) = 1 - p_1(t_i)$ and differentiating to solve for the optimal value $p_1^*(t_i)$.

PRIMARY AND SECONDARY SCREENING

In a security system comprising primary and secondary levels of screening, passengers arrive at screening where all passengers and carry-on baggage undergo primary screening using a set of routine detection devices. Then, a selected number of passengers are directed to undergo secondary screening, consisting of specialized devices and procedures, while the remaining passengers exit without receiving additional screening. Passengers are directed toward secondary screening, with probability $q(t_i)$, based on the passenger's assessed threat value and the secondary screening queue length at the time the secondary screening decision is made. This type of security system structure is utilized when CAPPS designates passengers as either selectees or nonselectees, for example.

Let the number of nonselectee and selectee passengers arriving at the security checkpoint, $N_{NS}^a(t)$ and $N_S^a(t)$, follow a Poisson process with rates $\lambda(1 - p_s) > 0$ and $\lambda p_s > 0$, respectively, where $0 \leq p_s \leq 1$ is the fraction of passengers who are designated as selectees. The total number of passengers arriving at the security checkpoint, $N^a(t) = N_{NS}^a(t) + N_S^a(t)$, is Poisson with rate $\lambda > 0$. Assume that if passenger i is designated as a selectee (nonselectee), then the observed passenger's assessed threat value is $\alpha_i = 1$ ($0 < \alpha_i < 1$). Furthermore, assume that the primary and secondary screening service times are exponential with rates μ_1 and μ_2 , security levels L_1 and L_2 , and capacities c_1 and

c_2 , respectively. Define the Bernoulli random variable $X(t_i) = 1(0)$ if passenger i is (not) directed to secondary screening.

The queueing process is sampled when each passenger enters the decision point for assigning secondary screening. Following the primary screening stage, optimization of the secondary screening assignment decision is equivalent to that of a two-class security system, where passengers assigned to the lower security class exit without further screening (i.e., $L_1 = 0, E[W_1(t_i)] = 0$, and $w_{\min} = 0$), while passengers assigned to the higher security class undergo the secondary screening procedures. Substitution of $L_1 = 0, E[W_1(t_i)] = 0$, and $w_{\min} = 0$ into Equations (5)–(7) simplifies the NLP to

$$\begin{aligned} & \text{minimize } (1 - \eta_1)(1 - q(t_i))^2 + \eta_1 q^2(t_i) \\ & \text{subject to } 0 \leq q(t_i) \leq 1, \end{aligned} \quad (8)$$

with solution $q(t_i) = 1 - \eta_1$. Since the fraction of nonselectee passengers is $1 - p_s$, the optimal probability for assigning (nonselectee) passenger i exiting primary screening becomes

$$\begin{aligned} q^*(t_i) &= 1 - \frac{p_1^*(t_i)}{(1 - p_s)} \\ &= \begin{cases} \frac{(1 - \eta_1)}{(1 - p_s)} & \text{if } s_2(t_i) < c_2 \\ 0 & \text{otherwise} \end{cases}, \quad i = 1, 2, \dots \end{aligned} \quad (9)$$

where $s_2(t_i)$ is the number of passengers in the queue for secondary screening at time t_i . Furthermore, $q^*(t_i) = 1$ if passenger i is designated as a selectee.

IMPACT AND LIMITATIONS OF PASSENGER SCREENING MODELS

Optimization of the passenger screening process is achieved by balancing the security and passenger throughput objectives via a cost weight parameter. This parameter can be qualitatively determined from current threat and environment factors to allow flexibility for either heightened security or expedited screening. Numerical solutions to the preceding NLP problems can be used to compare

security systems that partition the available detection devices into primary and secondary levels of screening versus those that partition the same set of devices into a two-class structure. This systematic approach to designing optimal screening strategies provides a unique perspective on the trade-off between security and passenger service, from which airport security operations personnel may use to fine-tune the security checkpoint process, expedite passenger screening, and further strengthen aviation security operation performance through an increase in the probability of threat detection. Incorporating a dual objective provides significant improvements in both air transportation safety and passenger satisfaction with the security screening process, and produces an automated system that is reliable, efficient, and cost effective. The results from this type of analysis play an important role in comparing different security screening structures, and provide a quantifiable means for presenting the benefits and limitations of each design to management officials within the aviation security sector.

Several mathematical assumptions place limitations on capturing the true behavior of the passenger screening process. In practice, service times do not follow an exponential distribution, since there exists a minimum amount of time to screen a passenger or bag. The screening process may be modeled using more complex service time distributions, which may also include either a time or queue length dependency on the service rate. Also, dependencies between the security classes can be modeled, where passengers who signal an alarm in one security class are directed to join the queue for a separate security class. This interaction would facilitate the use of highly specialized, time-consuming screening devices for high-risk passengers as well as for resolving alarms occurring from lower risk passengers. Lastly, optimization is performed over a security measure defined as the number of true alarms. In an effort to decrease cost and expedite screening, it is also desirable to minimize the number of *false alarms* (i.e., detecting a threat that does not exist) or minimizing the number of *false clears* (i.e., not detecting a threat).

However, there exists an inherent trade-off between minimizing the false alarm and false clear rates. These, as well as other alternative security measures, may be defined as objectives in the optimization problem.

ADDITIONAL OR TECHNIQUES IN PASSENGER SCREENING

In addition to queueing theory and non-linear programming, additional operations research techniques have been explored in related passenger and baggage screening research surrounding aviation security (see also the section titled “Anti-Terrorism and Homeland Security” in this encyclopedia). Discrete optimization models are used to develop policies that optimally screen passengers given a set of security screening devices [2]. Subsets of detection devices can be identified by solving an integer programming model, which defines multiple levels of security based on the device capacities within each security class. Each passenger is then assigned to a particular security class based on the perceived passenger’s risk level. Discrete optimization models have also been developed to sequentially assign passengers to a set of security classes, when the perceived passenger risk levels are known only upon check-in. Sequential passenger assignments are modeled as a Markov decision process, where the optimal policy for generating the set of assignments is obtained through dynamic programming [3], and also modeled as a discrete-time difference equation, where an optimal closed-loop passenger assignment algorithm is developed through both a probabilistic analysis and nonlinear control [4]. A two-stage model for a sequential stochastic security design problem analyzes the purchase of security devices and determines the screening assignments of sequentially arriving passengers, solved via a deterministic integer program [5]. Also, for sequential screening problems, a Bayesian analysis is used to incorporate prior knowledge of the device responses on a bag to develop metrics that assess the risk and cost associated with specific detection device configurations [6].

Linear programming models are used to investigate the benefit of dividing passengers into multiple levels of screening [7], with the objective of minimizing the number of false alarms, subject to a maximum false clear probability constraint. Extensions of this model accommodate various passenger risk levels and formulate the model as a mixed integer program [8], while also addressing the joint responses of the detection devices through a multivariate statistical analysis [9]. The deployment and utilization of new device technology can be addressed through the development of cost models to assess the risk and effectiveness among existing and proposed technologies [10–12]. Other applications of operations research techniques include the use of game theory to model the interaction between security system operations and terrorist-acquired knowledge of how the system behaves [13]. Further insight into the application of operations research techniques to aviation security issues can be found in the literature [14–16].

A key assumption in the trade-off between maximizing security and minimizing passenger screening times is that passengers become more dissatisfied with the security screening process the longer they wait to be screened. While many passengers may prefer to proceed through security with minimal hindrance, survey results indicate that many passengers also feel more secure when they experience a longer time in the screening process, given the thoroughness of passenger and baggage screening [17]. A statistical analysis studying the relationship between the waiting times of passengers at screening and their level of satisfaction with the screening procedures indicates that there exist factors other than waiting time that significantly affect the passengers' level of satisfaction [18]. The methodology employed throughout the research in aviation passenger screening provides the means to systematically address the problem of optimizing security given resource constraints. Resulting from various operations research techniques, priority can then be shifted readily between heightened security and expedited screening according to current threat and environmental factors.

OPTION PRICING: THEORY AND NUMERICAL METHODS

VOLODYMYR BABICH
BARDIA KAMRAD

Georgetown University,
Washington, DC

A *derivative security* is a contract whose payoff depends on the stochastic price of another security, called an *underlying asset*. For example, consider a contract which gives you the right to sell a share of IBM stock in three months for \$100. This contract, called *European put option*, provides you with an insurance against IBM stock price dropping below \$100. In three months, if IBM stock price, $S_{\text{IBM}} < \$100$, you can buy IBM stock for S_{IBM} and *exercise* the option, selling the stock for \$100, and pocketing the difference $\$100 - S_{\text{IBM}}$. If IBM stock price is $S_{\text{IBM}} \geq \$100$, you allow the option to expire unexercised. What is the “fair” price for this put option today? In this article, we will describe the models, theory, and numerical methods for pricing this put option and derivative securities in general.

There is a cornucopia of derivative securities, varying by the underlying assets, by the form of the flexibility, by payoffs characteristics, and so on. One distinguishes between *financial derivative securities*, which are traded on financial markets (see websites for CME Group—www.cmegroup.com, and CBOE—www.cboe.com), and *real options*, which are just various forms of flexibility that decision makers have. The basic types of financial derivatives are forwards, futures, swaps, and financial options. In this article, we will use stock options to illustrate ideas underlying the theory and practice of option pricing. The same ideas apply to other financial derivative contracts and (to some extent) real options, but implementation details could differ. Recommendations on reading about those details are at the end of this article.

The two most common financial option contracts are *call* and *put* options (in common parlance, they are referred to as *plain vanilla* put and call options). The call (put) option gives the owner a right to buy (sell) the underlying asset at the specified time in the future at the specified price, called the *exercise price*. In the example above, the *time to expiration* is three months, the exercise price is \$100, and the underlying asset is the IBM stock. Call and put options can be *American* or *European*. These are simply monikers. They do not reflect option geography. Similarly Russian, Israeli, Bermudan, and Asian options are not traded exclusively in Russia, Israel, Bermuda, and Asia. American options are allowed to be exercised at any time prior to the expiration time. European options can be exercised only at the expiration time.

In this article we will use the following notation: $S(t)$ - stock price at time t , T - time to maturity (time to expiration) of the option, K - strike price, $\Pi(S, t)$ - payoff of the option when it is exercised at time t and the stock price is S (for a put option $\Pi(S, t) = (K - S)^+$, where $(x)^+ = \max(x, 0)$; for a call option $\Pi(S, t) = (S - K)^+$), r - risk-free rate, μ - expected stock return, δ - dividend yield on the stock (continuous), σ - volatility (standard deviation) of stock returns, and $C(S, t)$ - value of the derivative security at time t , when the stock price is S .

In the next section we describe commonly used models for stock prices. Then we present no-arbitrage derivatives pricing and illustrate how no-arbitrage arguments work in case of binomial and Black–Scholes and Merton models. After that, we discuss numerical methods for derivative pricing: binomial and trinomial lattice, simulation, finite difference, and other methods. We conclude with suggestions for further reading.

STOCHASTIC PROCESSES AND STOCK PRICE MODELS

Derivative securities derive their value from the underlying asset price. The common

approach is to assume that the underlying asset price follows a stochastic process, with the dual attributes of “relevance” and “tractability.” In particular, the choice of a specific stochastic process must be plausible, it should capture salient statistical properties of the stock price, and it should facilitate the development of option pricing algorithms. For example, for stock prices plausibility implies nonnegative prices. A salient statistical features of stock prices is the *random walk* property, described as the statistical independence between successive stock returns. A consequence of the random walk property is the statement that, given the current stock prices, the future stock prices do not depend on the past prices, which is known as the *weak form market efficiency* hypothesis in finance, and *Markov property* in operations research (OR) and math (see the section titled “Diffusion Processes and Random Walks” in this encyclopedia). The following are several examples of Markov processes used to model stock prices.

Random Walks as Binomial and Trinomial Trees

Binomial and trinomial trees are examples of discrete-time Markov processes. Consider an equi-width partition $\{0 = t_0 < t_1 < \dots < t_N = T\}$ of time interval $[0, T]$ into periods, so that the length of each period is $\Delta t = t_{i+1} - t_i$, where t_i is an observation time, $i = 0, 1, \dots, N - 1$. Denote by $S_i = S(t_i)$ the stock price at time t_i , $i = 0, \dots, N$.

According to the binomial tree model, each period the stock price can go up with probability p or down with probability $1 - p$, that is for $i = 0, \dots, N - 1$

$$S_{i+1} = S_i Z_i, \text{ where } Z_i = \begin{cases} u & \text{with probability } p, \\ d & \text{with probability } 1 - p. \end{cases} \quad (1)$$

Random variables $\{Z_i\}_{i=0}^{N-1}$ are independent and they represent shocks to stock prices every period (stock price $S_i = s$ either jumps up to $S_{i+1} = us$ or down to $S_{i+1} = ds$). We assume that $u > d$. An example of a two-step binomial tree is given in the Fig. 1a.

If the current stock price is S_0 , after N steps along a binomial tree, the distribution of the stock price, S_N , is binomial. Specifically, random variable S_N takes value $S_0 u^j d^{N-j}$ with probability $\binom{N}{j} p^j (1-p)^{N-j}$ for $j = 0, 1, \dots, N$. When implementing binomial models, parameters u , d , and p are chosen so that the mean and variance of Z_i are equal to those of the stock return, over time step Δt . Thus, one has to solve a system of two equations and three unknowns, which has an infinite number of solutions. Cox *et al.* [1] were the first to use binomial trees for option pricing by imposing an additional constraint: $d = 1/u$. With this constraint, for a stock with the standard deviation of returns $\sigma\sqrt{\Delta}$, dividend yield $\delta\Delta t$, and mean return $\mu\Delta t$ over time Δt , binomial tree model

Figure 1. Binomial tree, two-step (left panel). Trinomial tree, one step (right panel).

parameters are

$$u = e^{\sigma\sqrt{\Delta t}}, d = e^{-\sigma\sqrt{\Delta t}}, \text{ and } p = \frac{e^{(\mu-\delta)\Delta t} - d}{u - d}. \quad (2)$$

The binomial tree nodes (price states) always recombine because the volatility is assumed homoscedastic (constant): that is, an up-state followed by a down-state will be in the same state (value) as a down-state followed by an up-state.

Kamrad and Ritchken [2] developed a trinomial lattice model accommodating a no-price-change as a possible state during a period of length Δt . That is for $i = 0, \dots, N - 1$,

$$S_{i+1} = S_i Z_i, \text{ where } Z_i = \begin{cases} u & \text{with probability } p_u, \\ 1 & \text{with probability } p_m, \\ d & \text{with probability } p_d. \end{cases} \quad (3)$$

Random variables $\{Z_i\}_{i=0}^N$ are independent and $p_u + p_m + p_d = 1$. Graphical representation of the trinomial model is given in the Fig. 1b. Similar to the binomial model, for a trinomial tree, parameters u , d , p_u , p_m , and p_d are chosen in order to match the first two moments of the actual stock returns. An extra degree of flexibility (compared to the binomial tree model, there is one extra variable in the trinomial tree model) affords more control over lattice implementation (i.e., jump sizes and probabilities, see the section titled “Numerical Methods in Derivatives Pricing.”) Kamrad and Ritchken [2] choose values for up and down jumps to be $u = 1/d = e^{\lambda\sigma\sqrt{\Delta t}}$ with the stretch parameter $\lambda \geq 1$ and the probabilities:

$$p_u = \frac{1}{2\lambda^2} + \frac{\left(\mu - \delta - \frac{\sigma^2}{2}\right)\sqrt{\Delta t}}{2\lambda\sigma}; \quad p_m = 1 - \frac{1}{\lambda^2}; \\ p_d = \frac{1}{2\lambda^2} - \frac{\left(\mu - \delta - \frac{\sigma^2}{2}\right)\sqrt{\Delta t}}{2\lambda\sigma}. \quad (4)$$

Geometric Brownian Motion

One of the most commonly used model for the evolution of the stock prices is the geometric Brownian motion (GBM) model, which is a continuous-time Markov process. The GBM model for stock prices is expressed as the following *stochastic differential equation*:

$$dS_t = (\mu - \delta)S_t dt + \sigma S_t dW_t, \quad (5)$$

where dW_t is an increment to the Wiener process, representing random shocks to stock returns.

The *Wiener process*, W_t , is a continuous-time stochastic process with satisfies the following properties: (i) $W_0 = 0$, (ii) independent increments, that is, for any $a < b \leq c < d$, $W(b) - W(a)$ and $W(d) - W(c)$ are independent, (iii) normality, that is, for any $b > a$, $W(b) - W(a)$ has a conditional (on $W(a)$) normal distribution with mean zero and standard deviation $\sqrt{b - a}$, (iv) path continuity, that is, any trajectory of W_t is continuous. Therefore, $dW(t)$ is a normal deviate with mean 0 and variance dt .

Informally, Equation (5) means that the percentage change in the stock price $\Delta S/S$ is due to the deterministic drift $(\mu - \delta)\Delta t$ and a random shock $\sigma\Delta W$. The rigorous definition and the solution of the stochastic differential equation (5) require tools of stochastic calculus [3–6]. Here, we simply present the solution (in the form similar to Equations (1) and (3)):

$$S_t = S_0 Z_t = S_0 e^{(\mu - \delta - \sigma^2/2)t + \sigma W_t}. \quad (6)$$

Therefore, for the GBM models of stock prices, for any t , random variable $\ln[S_t/S_0]$ is normally distributed with mean $(\mu - \delta - \sigma^2/2)t$ and standard deviation $\sigma\sqrt{t}$ or, in other words, S_t/S_0 follows the *log-normal distribution*. The binomial and the log-normal models of the stock prices are closely related. One can show that, as the number of subintervals N increases, the binomial model converges to the log-normal model [4, Chapter 3.2.7].

Other Models for Stock Prices

Although the GBM model is widely used in finance because of its mathematical properties, there is empirical evidence disproving its assumptions. Specifically, the GBM process (Eq. 5) is path continuous, but the movements of real stock prices are demonstratively discontinuous (see Cont and Tankov [7], Chapter 1). Next, the volatility parameter, σ , for real stock prices is not constant (e.g., French *et al.* [8]). Furthermore, the real stock returns may exhibit serial correlation, contrary to the independent increment property of the GBM process (see review by Richardson and Smith [9]). Finally, for real stock prices, $\ln[S_t/S_0]$ is not normally distributed because extreme movements of the stock prices happen much more frequently in practice than normal distribution allows (e.g., Jansen and de Vries [10]). To address the shortfalls of the GBM model, a number of alternative models have been considered, such as the constant elasticity of variance (CEV), stochastic volatility (SV), jump-diffusion, and Lévy processes. For discussion on alternative models for stock prices see Hull [11]. For theory and applications of Lévy processes Cont and Tankov [7]. As OR and management science academics and practitioners know, any model is just an approximation of reality and there is a constant tension between a model's precision and our ability to use the model for analysis. Therefore, it is likely that a variety of models, including the GBM model, will continue to be used to model stock prices.

NO ARBITRAGE DERIVATIVES PRICING

An *arbitrage opportunity* refers to a condition within financial markets such that a portfolio of traded securities exists, with the properties that (i) it can never generate negative cash flows to its holder, and (ii) it can generate positive cash flows with positive probability. In financial markets, arbitrage opportunities are short-lived in that supply and demand forces quickly dissolve price imbalances leading to such costless, riskless opportunities.

By disallowing arbitrage opportunities, we can limit the range of values that option prices can take. With additional

assumptions, we can derive a unique *no arbitrage* price. Typical assumptions made in no arbitrage analysis are the following: (i) Markets for stocks, bonds, and options are frictionless (no transaction costs; no bid-ask spreads; no restrictions on short sales; no taxes; shares of the stock are infinitely divisible); (ii) Markets are liquid (any position in financial securities is possible at any time); (iii) There are no arbitrage opportunities in the markets.

A typical derivation of no-arbitrage bounds on option prices proceeds as follows. One constructs a (replicating) portfolio comprising a short position in a risk-free asset such as T-bills and a long position in a number of shares of the stock. This portfolio is constructed in such way that all the cash inflow/outflow from this portfolio perfectly duplicates the option's cash flows during the maturity interval. Thus, the portfolio has the same exposure to the stock as does the option. Therefore, to avoid *arbitrage*, the option and the portfolio must command the same value.

No-arbitrage conditions guarantee the existence of a no-arbitrage option price. In addition, for uniqueness, we say that the market is *complete* when any derivative security's cash flows can be perfectly replicated through a combination of other existing traded assets at every point in time and for all possible states of nature. For complete markets, the no-arbitrage option price is unique and, in complete markets, options are redundant—it is always possible to construct replicating portfolios instead. In practice, however, options create tremendous economic value in terms of trading and financial market activity. We will demonstrate no-arbitrage pricing arguments on the binomial model and present the results of no-arbitrage analysis in the form of Black–Scholes and Merton option pricing formulas.

Binomial Model

Consider an economy with two assets: the stock and the bond. Suppose we would like to price a derivative security on the stock. Assume that stock price follows a one-step (for simplicity) binomial model (1) and bonds earn constant return r , continuously compounded (i.e., if the initial bond price is B_0 , at

time t this price is $B_t = B_0 e^{rt}$. Furthermore, for simplicity, the dividend yield on the stock is $\delta = 0$. One can prove that no-arbitrage condition in this economy is equivalent to $d < e^{rT} < u$.

To price the derivative security, first consider its time- T cash flows:

$$C(S(T), T) = \begin{cases} \Pi_u \stackrel{\text{def}}{=} \Pi(S_0 u, T) & \text{if } S(T) = S_0 u, \\ \Pi_d \stackrel{\text{def}}{=} \Pi(S_0 d, T) & \text{if } S(T) = S_0 d. \end{cases} \quad (7)$$

Create a portfolio by buying Δ shares of stock and investing b in bonds (note: Δ and b could be negative). This portfolio is replicating if the cash flows from this portfolio at time T (when portfolio is sold) match those from the derivative security:

$$\begin{cases} \Delta S_0 u + b e^{rT} = \Pi_u & \text{if } S(T) = S_0 u, \\ \Delta S_0 d + b e^{rT} = \Pi_d & \text{if } S(T) = S_0 d. \end{cases} \quad (8)$$

Because $u > d$, this system of equations has a unique solution (thus, our economy is complete):

$$\Delta = \frac{\Pi_u - \Pi_d}{(u - d)S_0}; \quad b = -e^{-rT} \frac{u\Pi_d - d\Pi_u}{u - d}. \quad (9)$$

Using these values, we compute the value of the portfolio to be

$$S_0 \Delta + b = \frac{\Pi_u - \Pi_d}{u - d} - e^{-rT} \frac{u\Pi_d - d\Pi_u}{u - d}. \quad (10)$$

To avoid arbitrage, this must be the price of the derivative security $C(S_0, 0)$ at time 0 (if this were not the case, e.g., the claim's price were lower, we would buy the claim and short the replicating portfolio, guaranteeing positive cash flow at time 0 and net zero cash flow at time T). Interestingly, after some algebra, Equation (10) can be written as

$$C(S_0, 0) = e^{-rT} \left[\frac{e^{rT} - d}{u - d} \Pi_u + \frac{u - e^{rT}}{u - d} \Pi_d \right]. \quad (11)$$

Define $q \stackrel{\text{def}}{=} \frac{e^{rT} - d}{u - d}$. Then, Equation (11) is the same as $C(S_0, 0) = e^{-rT} [q\Pi_u + (1 - q)\Pi_d]$. From no-arbitrage condition, $d < e^{rT} < u$, $q \in (0, 1)$. We will treat q as a probability, called the *risk-neutral probability*. Thus, $C(S_0, 0) = e^{-rT} E_q[\Pi(S(T), T)]$, where E_q is the expectation with respect to the risk-neutral probability.

The last observation is very important. It is an example of so-called *risk-neutral pricing*. Generally, no-arbitrage assumption implies the existence of a risk-neutral probability. Market completeness implies that this probability is unique. The “ $E = mc^2$ ” statement in financial asset pricing is that, in theory, any claim in the economy can be priced as $C(0) = E_q[e^{-rT} \Pi(T)]$, as long as one can find the appropriate risk-neutral probability measure. The challenge of asset pricing in practice is to find that probability measure.

For a binomial model with the continuous dividend yield, δ , the risk-neutral probability is

$$q = \frac{e^{(r-\delta)T} - d}{u - d}. \quad (12)$$

Note that the pricing formula (11) does not contain terms with the stock's expected return μ , the actual probability of stock going up, p , or any reference to the investor's risk preferences. It is as if all investors were risk-neutral and all assets were earning return of r . This explains the term *risk-neutral pricing*. The next section contains another illustration of risk-neutral pricing.

The Black–Scholes (1973) and Merton (1973) Option Pricing Model

Black and Scholes [12] and Merton [13], independently arrived at the same pricing formula that, in light of the assumptions made, governs the value of a European option. Our objective here is to provide an insight to and an intuitive understanding of the fundamental features of their model, absent mathematical rigor (a rigorous treatment can be found in many books [4,6]). We note that the B-S & M (1973) model can be derived in a number of ways including construction of a (self-financing, replicating) portfolio consisting of T-bills and shares of the stock, similar

to what was done for the binomial model above.

The set of assumptions required to derive the B-S & M (1973) model include the following: (i) Markets for stocks, bonds, and options are frictionless (no transaction costs; no restrictions on short sales; no taxes; shares of the stock are infinitely divisible). (ii) Risk-free rate of return, r is constant during the option's maturity $[0, T]$. (iii) Stock price process is given by Equation (5) with parameters μ , δ , and σ constant over the maturity interval $[0, T]$. We will demonstrate the model in the case of plain vanilla European options.

The analysis of the instantaneous change in the derivative security value ($C(S, t)$) over an instant of time results in a second-order partial differential equation (PDE), that is to be solved subject to the claim's terminal condition. This PDE and its solution is the B-S & M (1973) valuation model. The Black-Scholes PDE is (for $t \in [0, T]$ and $0 \leq S < \infty$)

$$\frac{\partial C}{\partial t} + \frac{1}{2}\sigma^2 S^2 \frac{\partial^2 C}{\partial S^2} + (r - \delta)S \frac{\partial C}{\partial S} - rC = 0. \quad (13)$$

Any European derivative on the stock satisfies Equation (13). However, claims differ in their terminal conditions. For example, for a European call option, the terminal condition is $C(S, T) = (S - K)^+$. For a European put option, the terminal condition is $C(S, T) = (K - S)^+$.

For a European call option, the solution of the B-S & M (1973) equation is

$$C(S, 0) = C_0 = Se^{-\delta T}F(d_1) - Ke^{-rT}F(d_2), \quad \text{where} \quad (14)$$

$$d_1 = \frac{\ln\left(\frac{S}{K}\right) + (r - \delta + \frac{\sigma^2}{2})T}{\sigma\sqrt{T}};$$

$$d_2 = \frac{\ln\left(\frac{S}{K}\right) + (r - \delta - \frac{\sigma^2}{2})T}{\sigma\sqrt{T}} = d_1 - \sigma\sqrt{T}. \quad (15)$$

In the above equations, C_0 is the B-S & M (1973) call value at time zero, and $F(\cdot)$ is

the cumulative standard normal probability. We are now in a position to provide some intuition to the model

1. Equation (13) is commonly referred to as the *fundamental equation*. A striking aspect of this PDE is the second-order effect: reflecting the rate of rate of change in the call relative to the stock and is proportional to the volatility of the stock (the partials with respect to the stock price and time are to be expected. The second-order effect results from stochastic calculus.)
2. In describing Equations (13) and (14), it is important to note the following:
 - a. The average growth rate of the stock, μ , does not appear in the model: the option's value is independent of μ regardless of the investors' risk preference. (In the derivation of the PDE (13) the term with μ gets eliminated.) This risk "preference" independence feature of the B-S & M (1973) model is a consequence of the risk-neutral valuation.
 - b. To obtain results, the B-S & M (1973) model requires five input parameters as given. These are initial stock price, $S(0)$; exercise price, K ; maturity time, T ; risk-free rate, r ; and volatility (standard deviation of the stock price return), σ .
 - c. In Equation (14), the constant dividend yield is taken (in effect discounted) out of the stock price. This is so because any dividend paid out accrues to the owner of the stock and not to the owner of the option. This adjustment is necessary to avoid arbitrage opportunities.
 - d. $F(d_2)$ is the probability that at its maturity the call option is exercised. That is, $F(d_2) = \Pr[S(T) > K]$. More on this below.
 - e. $F(d_1)$ is also a probability, as we will discuss below. It is commonly referred to as the *perfect hedge ratio* or the *option delta*: $F(d_1) = \frac{\partial C}{\partial S} = \Delta$. Option delta indicates the call's sensitivity to the stock price. A \$1

increase in the stock price will lead to a $\$ \Delta$ increase in the call value.

3. Stocks pay dollar dividends and not dividend yield.

B-S & M (1973) formula (14) can also be derived by simply computing the expectation in $C(S, 0) = E_q[e^{-rT}\Pi(S(T), T)]$, where E_q is the expectation with respect to the risk-neutral probability. Under the risk-neutral probability, the evolution of the stock price is given by the GBM model (5) with $\mu = r$. It is instructive to go through a few steps of this approach.

$$\begin{aligned} C(S, 0) &= E_q[e^{-rT}\Pi(S(T), T)] \\ &= E_q[e^{-rT}(S(T) - K)^+] \\ &= E_q[e^{-rT}(S(T) - K)1_{\{S(T) > K\}}] \\ &= E_q[e^{-rT}S(T)1_{\{S(T) > K\}}] \\ &\quad - E_q[e^{-rT}K1_{\{S(T) > K\}}] \\ &= E_q[e^{-rT}S(T)1_{\{S(T) > K\}}] \\ &\quad - e^{-rT}K \Pr[S(T) > K]. \end{aligned} \quad (16)$$

The last equality is based on $E_q[1_{\{S(T) > K\}}] = \Pr_q[S(T) > K]$ where $\Pr_q[\cdot]$ is the probability with respect to the risk-neutral measure. It is easy to compute $\Pr_q[S(T) > K]$ and verify that $\Pr_q[S(T) > K] = F(d_2)$.

It would be convenient to convert the expectation, $E_q[e^{-rT}S(T)1_{\{S(T) > K\}}]$, into an expression with probabilities. This transformation is possible by the change of *numeraire* technique. This technical step is frequently very useful in proofs of pricing formulas for many types of derivative securities, particularly securities on multiple assets, foreign exchange rates, and interest rates. Mathematical details can be found in a number of textbooks (e.g., Bjork [4] and Shreve [6]) and in Geman *et al.* [14]. Applications to option pricing of the change of numeraire technique are discussed in Schroder [15]. At a high level, the idea of the change of numeraire is as follows. Let $B(t) = e^{rt}$ denote the value of the money market account at time t (with $B(0) = 1$). Then pricing formula $C(S, 0) = E_q[e^{-rT}\Pi(S(T), T)] =$

$B(0)E_q[\Pi(S(T), T)/B(T)]$ compares the value of the option payoff with the value of money market account, which thus serves as a numeraire asset. But one does not have to use the money market account as a numeraire. Any positively valued asset $\beta(t)$ will work, and a general pricing formula is $C(S, 0) = \beta(0)E_\beta[\Pi(S(T), T)/\beta(T)]$, where E_β is the expectation with respect to the probability measure corresponding to the numeraire asset β (one can compute the Radon–Nikodym derivative of the new measure relative to the risk-neutral measure, but typically one simply uses the fact that the process $S(t)/\beta(t)$ is a martingale under the new measure [4,6,14]). For Equation (16), using this general pricing formula, we can write $E_q[S(T)/B(T)1_{\{S(T) > K\}}] = S(0)/B(0)E_S[1_{\{S(T) > K\}}] = S(0)\Pr_S[S(T) > K]$, where E_S ($\Pr_S$) is the expectation (probability) with the process $S(t)/B(t)$ as the numeraire. Further computations result in $\Pr_S[S(T) > K] = e^{-\delta T}F(d_1)$.

For a European put option, the solution of the B-S & M (1973) equation is

$$P(S, 0) = P_0 = Ke^{-rT}F(-d_2) - Se^{-\delta T}F(-d_1), \quad (17)$$

where d_1 and d_2 are given by Equation (15). The delta of put option is $\Delta = \frac{\partial P}{\partial S} = -F(d_1) < 0$. That is, as the stock price increases, the value of the put option decreases. $F(-d_2)$ is the put exercise probability.

American Options

The plain vanilla stock options traded on exchanges are American options. Recall that an American option can be exercised at any time prior to the option's expiration. The extra flexibility makes American options more valuable than the corresponding European options, but complicates the valuation process. Typically, there are no closed-form expressions, similar to Equations (14) and (17), available for American options. An exception to this is an American call option written on a nondividend-paying stock. One can show that it is not optimal to exercise this option prior to expiration. Therefore, the

additional flexibility of the American feature is worthless; the value of an American call option is equal to the value of the corresponding European call option, and is given by formula (14). Note that it can be optimal to exercise an American put option on a nondividend paying stock early and, therefore, we cannot use formula (17) for American put options.

One approach to valuation of American options is to identify a region $R \subset \mathbf{R}_+ \times \mathbf{R}_+$ in the space of stock prices and times (S, t) , where the exercise of the option is optimal. Inside of the exercise region (i.e., for $(S, t) \in R$), the value of the option is equal to the option's payoff ($C(S, t) = \Pi(S, t)$). Outside of the exercise region, the value of the option satisfies the B-S & M (1973) PDE (13). Because, when solving the PDE (13), we do not know in advance where the boundary (∂R) of the exercise region (R) lies, to value an American option we need to solve a *free boundary problem*. An additional condition used to describe the free boundary problem for American options is the *smooth pasting condition*, that is $\frac{\partial C(S, t)}{\partial S} = \frac{\partial \Pi(S, t)}{\partial S}$ for all $(S, t) \in \partial R$. The smooth pasting condition is a no-arbitrage condition—it is necessary to avoid arbitrage opportunities in the model. When an American option does not have an expiration time, the free boundary problem is simplified because the B-S & M (1973) PDE (13) becomes an ordinary differential equation (ODE):

$$\frac{1}{2}\sigma^2 S^2 \frac{\partial^2 C}{\partial S^2} + (r - \delta)S \frac{\partial C}{\partial S} - rC = 0, \quad (18)$$

yielding closed-form expressions for option prices (see Dixit and Pindyck [16]). However, when an option has a finite life T , the option value can be found only numerically (see discussion of numerical methods in the section titled “Numerical Methods in Derivatives Pricing”).

Another approach to valuation of American options is to combine the optimal stopping problem with the risk-neutral pricing. Mathematically, the exercise time of an American option is a *stopping time* (for definition and properties of stopping times, see Oksendal [3]). If $\Theta[t, T]$ is a set

of all stopping times $\theta \in [t, T]$, then the value of an American option at time t is found by solving an optimization problem $C(S(t), t) = \sup_{\theta \in \Theta[t, T]} E_q [e^{-r(\theta-t)} \Pi(S(\theta), \theta)]$, where, as before, E_q is the expectation with respect to the risk-neutral probability. The solution of this optimization problem requires tools beyond the scope of this introductory article (please, see Oksendal [3], Shreve [4], and the section titled “Martingales” in this encyclopedia for the discussion of the solution to the optimal stopping problem, *martingales*, and *supermartingales*). We would like to mention, in passing, that one can solve the optimal stopping problem (and, hence, value American options) using variational inequalities (see **Variational Inequalities** and Oksendal [3]). For further discussion of variational inequalities and other approaches, see a review article by Broadie and Detemple [17].

NUMERICAL METHODS IN DERIVATIVES PRICING

For some options, such as European put and call options, there exist closed-form pricing formulas (Black–Scholes formulas (14) and (17)). However, for the majority of derivative securities, both European and American types, valuation can be done only numerically. In this section we will discuss several numerical methods commonly used for option pricing: binomial and trinomial trees, simulation, and finite difference methods.

LATTICE MODELS

Binomial lattice (binomial tree) model of Cox *et al.* [1] is one of the most commonly used models. Its main strengths are simplicity and flexibility. It can be easily understood and programmed and it is difficult to make a mistake implementing it. Lattice models can be used to price practically any type of option and, compared to other models, they are particularly easy to use for pricing American options. The drawback of lattice models as numerical algorithms is that they tend to be slow, particularly for options which depend on several underlying assets. With lattice methods, the objective is to approximate the

stochastic evolution of the underlying asset over the maturity interval $[0, T]$. The lattice generates possible states of price realization in discrete-time steps with corresponding probabilities (see the section titled “Random Walks as Binomial and Trinomial Trees”). The state space and the probabilities are constructed in a manner to ensure convergence to the continuous-time stochastic process and eliminate arbitrage opportunities (see the section titled “Binomial Model”). With the lattice, the option’s terminal condition is superimposed on the final set of approximating stock price states and terminal option values are approximated. A backward stochastic *dynamic programming* recursion is then used to obtain the time-zero option value (for further discussion of dynamic programming, see the section titled “Markov Decision Processes” in this encyclopedia). If the option is American, then for every node on the tree, we simply compare the value computed by backward recursion and the exercise value of the option and select the larger of the two. The trinomial tree method is applied similarly.

Simulation

Monte Carlo simulation methods (see the section titled “Monte–Carlo Method” and “Markov Chain Monte–Carlo” in this encyclopedia) use the representation of option prices as the expected discounted option payoffs (with respect to the risk-neutral measure; see the section titled “No Arbitrage Derivatives Pricing”), that is, $C(S, 0) = E_q[e^{-rT}\Pi(S(T), T)]$. The main idea of simulation methods is to approximate the expectation by the sample mean of the sample generated from the random variable $e^{-rT}\Pi(S(T), T)$.

For example, to price the put option introduced at the beginning of this article, we (i) generate a sample of IBM stock prices at time $T = 3/12$: $\{S_1(T), S_2(T), \dots, S_N(T)\}$; (ii) compute discounted option payoff at each value of the IBM stock price: $\{\pi_1 = e^{-rT}\Pi(S_1(T), T), \pi_2 = e^{-rT}\Pi(S_2(T), T), \dots, \pi_N = e^{-rT}\Pi(S_N(T), T)\}$, where $\Pi(S, t) = (100 - S)^+$; and (iii) use sample mean as an approximation of the expectation: $p = \sum_{i=1}^N \pi_i / N$.

By the central limit theorem, this approximation converges to the true value of the expectation with the rate of $O(1/\sqrt{N})$. The convergence rate remains the same even if the option payoffs depend on the values of more than one underlying asset: $\Pi[S^1(T), S^2(T), \dots, S^M(T), T]$. As the dimension of the problem, M , increases, the computational effort for generating additional random variables increases more slowly than the computational effort for computing M -dimensional integrals using other numerical methods. Therefore, for high-dimensional problems, Monte Carlo simulation methods outperform other numerical methods.

To generate a sample $\{S_1(T), S_2(T), \dots, S_N(T)\}$ of the IBM stock prices, we invoke one of the stochastic models for stock prices (see the section titled “Stochastic Processes and Stock Price Models”). For example, for the GBM model, we generate a sample of independent standard normal random numbers $\{z_1, \dots, z_N\}$ and, using Equation (6), construct a sample of IBM stock prices as follows: $\{S_i(T) = S_0 e^{(r-\delta-\sigma^2/2)T + \sigma\sqrt{T}z_i}\}_{i=1}^N$. Note that, in Equation (6) the expected stock return μ was replaced by the risk-free rate, r , because the stock price process is considered under the risk-neutral measure.

Monte Carlo simulation is a very flexible method that can be used to price many types of options. In particular, Monte Carlo simulation works well for path-dependent options, such as Asian, barrier, and lookback options (see Boyle *et al.* [18], and Moel and Tufano [19]). Path-dependent options are examples of so called *exotic* options. Recall that the payoff for the European put option discussed at the beginning of this article is $[K - S(T)]^+$, where K is the strike price and $S(T)$ is the stock price at the expiration time. In contrast, the payoff of an Asian put option is $[K - A(T)]^+$, where $A(T)$ is the average price of the stock during time $[0, T]$. The payoff of a barrier option depends on the event of the stock price reaching a barrier during the life of the option. An *up-and-out put* option, for instance, has the same payoff as a regular European put option, $[K - S(T)]^+$, unless the stock price rises above the specified barrier, b , during time $[0, T]$, in which case the option becomes worthless. The payoff of a lookback

option depends on the highest or the lowest stock price during time $[0, T]$, and not just the price $S(T)$.

Monte Carlo simulation also works well for pricing derivatives that depend on several underlying assets, such as spread options, rainbow options, and outperformance options (e.g., Carmona and Durrleman [20]). For example, a rainbow option payoff is equal to $[S_1(T) + S_2(T) + \dots + S_L(T) - K]^+$, where $\{S_l\}_{l=1}^L$ are underlying assets.

The standard error of Monte Carlo simulation is $\sigma_p/\sqrt{N}$, where σ_p is the sample standard deviation of the sample of option payoffs, and N is the sample size. The standard error is reduced if the sample size, N , increases, but only at the rate of $\sqrt{N}$. Alternatively, one can reduce σ_p part of the standard error by applying *variance reduction techniques*, such as *control variates*, *moments matching*, *antithetic variables*, *stratified sampling*, and *importance sampling* (see the section titled “Variance Reduction Techniques” in this encyclopedia). The implementation of the variance reduction techniques is relatively simple and the computational improvements are significant. Therefore, in practice some form of the variance reduction technique is usually applied when using Monte Carlo simulation.

Monte Carlo simulation methods become computationally expensive when applied to pricing of American options. As discussed

earlier, American options can be exercised at any time during the life of the option. The interaction between the option exercise optimization problem (given the simulated asset prices) and the simulation of the option payoff (for the optimal option exercise) leads to considerable computational difficulties. Therefore, typically, other numerical methods are used for American option pricing (although simulation-based algorithms have been proposed, e.g., Longstaff and Schwartz [21]). For further discussion of the Monte Carlo simulation see Glasserman [22].

Finite Difference Methods

To solve Black–Scholes PDE (13) using a finite difference method, we begin by discretizing the time and stock price spaces. Specifically, consider time points $t = j\Delta t$, for $j = 0, 1, 2, \dots, J$ and stock values $S = i\Delta S$, for $i = 0, 1, 2, \dots, I$. These points make up a grid where Δt and ΔS are time and price steps and $J\Delta t = T$, see Fig. 2. The option value at any grid point $(S, t) = (i\Delta S, j\Delta t)$ is denoted by $C(i\Delta S, j\Delta t) = C_i^j$.

Next, we replace partial derivatives in PDE (13) by their discrete approximations (called *finite difference approximations*). There are a number of finite difference approximations. For example, $\frac{\partial C}{\partial t}(i\Delta S, j\Delta t) \approx \frac{C_i^j - C_i^{j-1}}{\Delta t}$, $\frac{\partial C}{\partial t}(i\Delta S, j\Delta t) \approx \frac{C_i^{j+1} - C_i^j}{\Delta t}$, and $\frac{\partial C}{\partial t}(i\Delta S,$

Figure 2. Graphical representation of an explicit (a) and an implicit (b) difference methods. Filled circles represent grid nodes where option values have been already computed. Circles with a question mark represent grid nodes where option values are being evaluated.

$j\Delta t) \approx \frac{C_i^{j+1} - C_i^{j-1}}{2\Delta t}$ are called *backward*, *forward*, and *central difference approximations* for $\frac{\partial C}{\partial t}$, respectively. The finite difference approximations of $\frac{\partial C}{\partial S}$ are defined similarly.

The second-order partial derivative is usually approximated as $\frac{\partial^2 C}{\partial S^2}(i\Delta S, j\Delta t) \approx \frac{C_{i+1}^j - 2C_i^j + C_{i-1}^j}{\Delta S^2}$. The forward, backward, and central differences possess different numerical properties (e.g., errors using forward and backward differences are of $O(\Delta S)$ and $O(\Delta t)$, whereas the error using central differences are of $O(\Delta S^2)$ and $O(\Delta t^2)$) and the properties of the finite difference method depend on which approximations are used.

We use option payoff, $\Pi(S, T)$, to specify option values at $j = J$. We also specify boundary conditions for $i = 0$ and $i = I$. Using backward finite difference in time and central difference in stock price and collecting terms C with same indices, PDE (13) is approximated by

$$C_i^{j-1} = a_i^j C_{i+1}^j + b_i^j C_i^j + c_i^j C_{i-1}^j, \quad (19)$$

where coefficients a_i^j , b_i^j , and c_i^j do not depend on the option prices, C . From conditions at expiration and boundary condition we know values C_i^J , for $i = 1, \dots, I$. Using Equation (19), we can compute values C_i^{J-1} for $i = 1, \dots, I$. Continuing this process recursively we derive C_i^0 for $i = 1, \dots, I$. Because option price C_i^{j-1} depends only on option prices which are already known: C_{i+1}^j , C_i^j , and C_{i-1}^j , the finite difference method corresponding to the difference equation (19) is called the *explicit difference method*. This explicit difference method is represented in Fig. 2a. Note that Equation (19) is equivalent to a relationship between option prices in a trinomial tree. Just as with the trinomial tree, if the option is American, then for every node, we simply choose the larger of (i) the option exercise value, and (ii) the value from Equation (19).

Using forward finite difference in time and central difference in stock price and collecting terms C with the same indices, PDE (13) is approximated by

$$d_i^j C_{i+1}^j + e_i^j C_i^j + f_i^j C_{i-1}^j = C_i^{j+1}. \quad (20)$$

This equation combines several unknown option prices (with superindex j) and is called an *implicit equation*. The corresponding implicit method is shown in Fig. 2b. By solving a system of linear equations of the form (20) together with boundary conditions and conditions at the expiration, one derives the option values at every point of the grid.

Implementation of implicit difference methods requires more programming sophistication than implementation of explicit methods. Fortunately, numerous software packages offer efficient routines for solving linear systems of equations. Implicit methods have one significant advantage over explicit methods—numerical stability (which roughly means the insusceptibility of an algorithm to accumulation of rounding errors). One can prove that an explicit method above is stable (and therefore generates an answer which is not dramatically affected by rounding errors) only if $\Delta t < A\Delta S^2$, where constant A can be computed. This constraint on the time step relative to the price step is a significant hindrance in practice, because small Δt translates into dramatic increase in the number of computations one needs to perform to find the option price. Implicit methods are numerically stable without any restrictions on the size of the time step. For additional discussion on the use of finite difference methods for option pricing, see Wilmott [23, Chapters 63–65].

Other Methods

Besides finite difference methods, there are many methods for solving PDEs [24]. Many of those approaches, specifically Laplace and Fourier transforms and expansions in Fourier and Taylor series, have been used for option pricing [25–28].

FURTHER READING

Quantitative finance, and derivative pricing in particular, is a vibrant research and applications area. New approaches are discovered and new models are introduced almost as quickly as the new types of derivative securities are invented. In this article we touched on only a small subset of important

ideas. Fortunately, there is a multitude of websites, articles, and books available to help those who are interested in derivatives. Comprehensive and accessible introductions to derivatives and derivative pricing can be found in Broadie and Detemple [17], Wilmott [23], Ritchken [29], Briys *et al.* [30], Wilmott *et al.* [31], and Hull [11]. Discrete-time arbitrage pricing is presented in Pliska [32] and Shreve [33]. Stochastic calculus and its applications in continuous-time finance are described in Oksendal [3], Shreve [4], Karatzas and Shreve [5], Björk [6], and Steele [34]. Commodity derivatives are discussed in Geman [35]. For models of interest rates and pricing of interest rate derivatives, see Jarrow [36]. Credit risk, credit derivatives, and credit derivatives pricing are presented in Schönbucher [37]. Real options are discussed in Dixit and Pindyck [16], Trigeorgis [38], Grenadier [39], Schwartz and Trigeorgis [40] and in the section titled “Value of Information and Option Values” in this encyclopedia. For a review of empirical research of stock and option price processes, see Bates [41].

Transportation services are the backbone of the economy and a vital parameter to help gauge the growth of a country. A streamlined flow of raw materials to production facilities and finished products to customers through different transportation modes (rail, road, air, and water) aids in market stability. Rail has always shared a major role in freight transport. After the deregulation act (Staggers Rail Act, 1980) and subsequent technological improvement, the US freight railroad's traffic volume has increased by almost 50%. On average, a typical Class I US railroad (BNSF, CN, CP, CSX, FFX, KCS, NS, TFM, and UP) receives about 4000–7000 new shipments (carloads) from its 5000 customers every day. These shipments are moved from some 1000 origins to about 2000 destinations. This steep rise in the demand coupled with higher customers' expectations has created the need for better resource planning in order to provide more efficient and cost-effective services.

The services can be improved by capacity expansion, which is capital extensive, and/or by optimizing the constituent operations, which we discuss in this article. A major railroad comprises more than 10,000 miles of tracks, with several thousand trains moving along them weekly. These trains include about 2000–3000 locomotives and approximately 80,000 railcars located in

about 200–300 rail yards, requiring more than 5000 crew members to operate. Because further expansion in the infrastructure would not prove cost effective, the second approach of implementing optimization-based rules of planning and scheduling is more practical. However, the railway system is by nature highly complex because of its interlinked subsystems (locomotives, railcars, crews, tracks, etc.). Each individual subsystem comprises very large scale optimization problems which render the standard solution techniques unusable. Most of the recent research papers on this topic deal with simplified models, or apply them to unrealistic or isolated instances. In addition, collecting and organizing the data required for implementing and installing software in the railroad industry is an arduous task. However, the situation is gradually improving with the development of effective and practical algorithms, and railroads have started implementing operations research (OR)-based decision tools because of the pressure of a competitive environment. Recently, Canadian Pacific Railways was chosen as the winner of the 2003 Franz Edelman Award for achievement in operations research and management sciences for their project titled, "Perfecting the Scheduled Railroad: Model-Driven Operating Plan Development" [1]. This project generated a cost savings of approximately US\$ 170 million between 1999 and 2000.

With the rapid development of other modes of transportation, the concept of "running a scheduled railroad" has gained increased importance. The traditional tonnage-based approach attempts to save costs by focusing on reducing the number of trains and creating longer trains, even if that causes delays or cancellations of scheduled trains. This differs from the modern "schedule-based approach," in which trains follow the operating plan even if they are not fully loaded. Although the current approach is more favorable for customers, several operating issues may arise without a dedicated

planning and scheduling optimization tool. Examples of such issues include: scheduling extra trains to meet the deadlines; more congested tracks and yards; increased idle time of expensive equipment (e.g., \$1 million locomotives, \$65,000 railcars); additional maintenance; and consequently a risk of higher operating costs.

In this article we discuss cutting-edge mathematical models and state-of-the-art algorithms for solving the enormous, immensely complex, and commonly interrelated problems arising from the above-mentioned issues. The decision-making issues arise at each level of planning: (i) strategic: design of track network; increasing line capacity; location of track sidings; building new yards, improving existing yards, and closing outdated yards; plus sizing and updating the fleet of locomotives and railcars; (ii) tactical: developing train and locomotive schedules, maintenance schedules, empty railcars and containers repositioning schedules; and (iii) operational: crew management; yard operations such as switching, consist-busting/formation, and so on. Also, we review the planning-related optimization problems (train planning, locomotive planning, and crew planning) which have been effectively solved using OR-tools, and implemented at various railroad companies that showed significant quantitative as well as qualitative benefits. We describe each problem in detail including the unique characteristics which make it so challenging.

A train consists of blocks of railcars with different origins and destinations, a set of locomotives to pull the railcars, and a set of crews to operate it. From the demand side, each major railroad may receive 4000–7000 new shipments every day, with each shipment consisting of a set of railcars with a common origin and destination [2]. These shipments are grouped together according to a blocking plan; each shipment, or block, is shipped as a single unit. Adhering to blocking plans helps to minimize the total transportation and handling costs. After the blocking plan is prepared, the next task is to develop train schedules (master schedule) in order to determine the train routes, their frequencies,

and the days of operation for each train. The master schedule is critical in minimizing the block carrying cost. Detailed timetables are then developed using several operational and safety constraints with a goal of limiting the total deviations and delays (train dispatching or meet-and-pass problems) from the master schedule. We study these three closely related problems in depth in the section titled “Train Planning.”

The section titled “Locomotive Planning” covers the locomotive planning problem and specifically deals with providing enough power to the scheduled trains by efficiently assigning and routing them over the network. A number of factors must be considered, such as fleet-size constraints on different locomotive types, fueling and maintenance restrictions, as well as matching restrictions between trains and locomotives. At the tactical level, besides deciding on the type of locomotives used, we also balance their availability throughout the network by deadheading (pulling locomotives from one place to another attached to scheduled trains such as railcars), or light travel (locomotives traveling on their own and not pulling any railcar). At the operational level, we assign specific units from the available set of locomotives to the scheduled trains.

After the train and locomotive planning is completed, crews are assigned to each train to execute these plans. The crew planning aspect is one of the most difficult challenges of railroads, similar to the problems experienced in the airline industry, owing to the presence of union rules in addition to other operational constraints (see the section titled “Crew Planning”). The objective is to assign crews to each train and maintain a balanced availability at each location in order to avoid crew-related delays so that crew costs are minimal.

Infrastructure modifications do not occur frequently in railroads, but the industrial revolution and subsequent changes have created the need to upgrade. A vast amount of literature exists on these related topics, such as finding rail-yard locations and track maintenance problems. Yard location is one of the foremost strategic-level concerns. The objective is to find the best possible locations

for the yards (venue for blocks classification and train switching) over the network, so that effective blocking plans can be developed. Another variation of this problem is to assess the effect of closing an existing yard on the railroad's overall performance, such as the impact on transportation cost. An optimally planned yard network has the potential of saving millions of dollars every year, as it reduces the number of handlings and helps in improving the blocking plan. We refer the readers to the papers by Ahuja *et al.* [3] for the details on this topic.

The freight trains carry tens of thousands of tons of weight and run at a very high speed. The tracks supporting these operations must have regular maintenance to ensure their safe and optimum performance. Nemani *et al.* [4] discuss the problem of preparing an annual timetable for the maintenance-crews to complete the track repair or replacement jobs (curfew planning). It is a highly constrained problem with a large number of restrictions, such as the number of regions being repaired simultaneously; work-continuity (no crews should be idle anytime except during vacations); and schedule development that minimizes the number of constraint violations. The paper discusses several exact and optimization-based heuristics to solve the problem.

In this article, we skip the infrastructure related problems and focus on the scheduling and planning of railcars, locomotive, and crews. In the following sections we discuss each of these problems, along with approaches for solving them.

TRAIN PLANNING

Train planning involves a myriad of decisions, from the arrival of customer orders (railcars) at the origin to delivery at their destination points, with intermediate attaching and detaching to existing trains along the route. In this section, we study three of the most complex and closely interrelated problems, which are solved sequentially to generate a train plan: railroad blocking, train scheduling, and train dispatching.

Railroad Blocking Problem

Railroad blocking is a classification problem which aims to reduce costs primarily through minimizing the intermediate (between origin and destination) handling of railcars. Each railroad receives thousands of shipments (set of railcars) everyday at its yards to ship between their origin–destination (O–D) pairs. Ideally, each shipment should be handled individually and transported via the shortest path between the O–D pair. However, the resources available at yards (crews, classification tracks, and switching locomotives) limit the classification capacity and render individual handling infeasible. Besides, scheduling a direct train between each O–D pair without any intermediate handling is impossible considering the huge railroad network. The small amount of freight for many O–D pairs and the limited rail network structure also encourage the consolidation of overall network. Therefore, several shipments are grouped into one block and transported between the block's O–D pair as a single unit. A block O–D pair may be different from the O–D pairs of individual shipments, so shipments may require reclassifications at intermediate yards. For example, suppose two shipments originating at the Jacksonville (JAX) yard have destinations of Los Angeles (LA) and San Diego (SD), respectively. Both can be grouped with other shipments headed for California, into a block with the O–D pair as JAX–LA. At LA, another block will be created with all shipments arriving at LA and headed to SD. In this example, the shipments with the O–D pair JAX–SD are transported by grouping them into two blocks with different O–D pairs.

It should also be noted that once a shipment is placed in a block, it will not be classified again until it reaches the destination of that block. The classification process often induces a one-day delay for the shipment, causing a potential bottleneck. Besides the indirect cost of delay, the (re)grouping costs are also substantial. For a typical railroad, the average cost of reclassification is \$40 per car. Assuming that a railroad ships 50,000 shipments per month, on average each

containing 10 cars and requiring 2.5 classifications, it would require six million cars per year costing approximately \$1 billion for the classification process. Even a minor reduction in these costs by employing OR-based tools will save tens of millions of dollars for a single US railroad company.

Mathematical Models. In the past, several researchers have attempted to solve the blocking problem by using mathematical models or some heuristics [5–9]. They use network-based models to formulate this problem, albeit with limited success from an implementation point of view. We briefly describe a *multicommodity flow* [10] based model, along with its limited applicability, followed by an implementable solution approach.

Let $G = (N, A)$ be the blocking network, where N is the set of all nodes denoting origin, destinations, or intermediate stations and A is the set of all potential arcs in $N \times N$, that is, $(i, j) \in A$ if a block can be built from node i to node j . The classification cost of a car is h_i and the cost of shipping a block through arc (i, j) is c_{ij} . We need to determine: (i) y_{ij} : which arcs to build, and (ii) x_{ij}^s : the flow of each shipment s of set S (collection of all shipments, containing n_s cars) on each arc (i, j) .

We develop a blocking model with the objective of minimizing all flow and handling costs (Eq. (1)), honoring several operational and modeling constraints. The problem requires that all n_s cars of a shipment s of set S , must be sent along a unique path (Eqs (2) and (7)). The resource availability restricts the maximum number of blocks, b_i , made at a node $i \in N$ (Eq. (4)), as well as the maximum number of cars, d_i , it can handle (Eq. (5)). The geometric configuration does not allow more than a specific number, u_{ij} , of cars to pass through the arc (i, j) of the network (Eq. (3)). Let $I(i)$ and $O(i)$ be the set of incoming and outgoing arcs of node i , respectively; $o(s)$, and $d(s)$ denote the origin and destination of s , respectively. All these notations will be followed throughout the article

unless otherwise stated.

$$\text{Minimize } \sum_{s \in S} \sum_{(i,j) \in A} c_{ij} x_{ij}^s + \sum_{i \in N} \sum_{s \in S} \sum_{(i,j) \in O(i)} h_i x_{ij}^s \quad (1)$$

$$\text{subject to } \sum_{(i,j) \in O(i)} x_{ij}^s - \sum_{(i,j) \in I(i)} x_{ij}^s = \begin{cases} n_s, & \text{if } i = o(s) \\ 0, & \text{if } i \neq o(s) \text{ or } d(s), \forall s \in S \\ -n_s, & \text{if } i = d(s) \end{cases} \quad (2)$$

$$\sum_{s \in S} x_{ij}^s \leq u_{ij} y_{ij}, \forall (i, j) \in A \quad (3)$$

$$\sum_{(i,j) \in O(i)} y_{ij} \leq b_i, \forall i \in N \quad (4)$$

$$\sum_{s \in S} \sum_{(i,j) \in I(i)} x_{ij}^s \leq d_i, \forall i \in N \quad (5)$$

$$y_{ij} \in \{0, 1\}, \forall (i, j) \in A \quad (6)$$

$$x_{ij}^s \in \{0, n_s\}, \forall (i, j) \in A, \forall s \in S. \quad (7)$$

A class I railroad on average receives 50,000 shipments (each containing 1–50 cars) at approximately 1000 origins, 300 yards, and 2000 destinations every day. The number of possible blocks for this network will be around one million (between each origin-yard pair, each yard-yard pair, and each yard-destination pair), pushing the total number of decision variables into the billions. The exponential size of the instances eliminates the use of any standard exact optimization model and encourages the use of heuristics to find near-optimal solutions in a reasonable time frame. We describe a very large scale neighborhood search algorithm for blocking problems, which has been successfully implemented at several railroads.

Very Large Scale Neighborhood (VLSN) Search Algorithm. The VLSN search algorithm is a variant of the local search algorithm that effectively explores the exponentially large neighborhood and converges to a good near-optimal solution. It is applicable to only those problems that can be expressed as an instance of partition problems [11]. Through the course of

developing algorithms for blocking problem, we observed that in most cases honoring the blocking capacity (b_i) at each yard is enough to ensure its car-handling limit (d_i) and maximum flow constraints on arcs (u_{ij}). Hence, these constraints can be ignored for all practical purposes and can be handled using the Lagrangian relaxation approach [10]. We also observe that these relaxations reduce the problem to finding only the arcs to be built, as all capacity constraints have been relaxed. Once the arcs are built, flows on each arc can be found by determining the shortest path for each shipment. The VLSN algorithm uses these concepts in its two-phase approach: (i) construction phase and (ii) improvement phase.

The construction phase aims to find an initial solution, which will form the basis for the improvement phase. The initial solution must be feasible. Therefore, it should ensure that the origin node of each shipment is connected to its destination node through a blocking path without violating the blocking capacity of any node. We obtain this solution in four simple steps: (i) construct a directed cycle that passes through all the yards exactly once and returns to the first yard; (ii) create a blocking arc from each origin node to the nearest yard; (iii) connect each destination node to the nearest yard that still has some blocking capacity; and (iv) route shipments along the shortest path over the network. The initial solution is then improved in the second phase by searching for better solutions in its neighborhood.

Creating the neighborhood structure is an art and the success of a neighborhood search algorithm is dependent on it. The neighborhood of a blocking problem is constructed by changing the blocks made at a single node and re-solving the shortest path problems on an updated arc-set. Clearly the neighborhood size is very large, as there are N nodes to choose from; for each node with p emanating arcs, there are pC_k ways in which a subset of k arcs can be selected. The problem of finding a better solution in this neighborhood is NP-complete and hence, an explicit search in a reasonable time frame is impossible. A heuristic algorithm has been developed by

Ahuja *et al.* [5], which uses a five-step subroutine at each node i : (i) delete all arcs emanating from node i ; (ii) reroute the flow on the updated arc-set; (iii) create one new arc at a time from node i and determine the potential savings, assuming no change at other nodes; (iv) add each new arc to the network that provides maximum savings; and (v) repeat steps (iii) and (iv) until the blocking capacity is met or all options are exhausted.

The proposed algorithm is very flexible in accommodating new constraints based on a variety of scenarios at different railroads. Some railroads may not want to deviate from their existing plans by more than a specific value, and hence fix several blocks in the input. They may also want to send a shipment through a specific route. Owing to demand patterns in a special direction and other external factors (empty car repositioning), they may want blocks to travel only in a specific direction between two nodes. Several such scenarios have been considered in the article by Ahuja *et al.* [5].

Conclusions. The proposed VLSN search algorithm has been tested and implemented at three large US railroads. Each railroad has realized significant reductions in their average car miles (0.1–4%), and in the number of reclassifications (31–42%) at the yards over their manual plans. The dynamic nature of the problem also restricts the computational time. The VLSN algorithms proved very effective on this front too, by solving different instances between 5 min and 2 h.

After a blocking plan is prepared, developing a train schedule is the next most important operational planning task. To realize the savings mentioned above, a proper match between the train schedules and blocking plan is required. In the next section, we discuss this problem and offer several solution approaches.

Train Scheduling Problem

A train schedule is a detailed description of the train routes, their frequencies, and their timetables on the railroad's network designed to minimize the cost of carrying cars

Figure 1. Structural components of a train scheduling problem.

from their origins to destinations. Figure 1 shows a simple example of a railroad network with nine nodes (stations), three trains and block paths. Train t_1 starts at node 1, follows the route 1–2–5–7, and terminates at node 7. Train t_2 follows the route 1–3–4–7, and train t_3 traverses the path 3–6–7. Three blocks of cars, b_1 , b_2 , and b_3 , travel on these trains. Block b_1 takes train t_1 over the train segments 1–2–5, while block b_2 takes the same train over the segments 2–5–7. As a train travels from its origin to destination, it picks up blocks at various nodes it visits and may also drop off blocks at those nodes. Typically, several blocks ride on a train at any segment. Likewise, a block may travel on several trains as it goes from its origin to its destination. For example, block b_3 starts at node 1 and travels on train t_2 on the segment 1–3. It is off-loaded by train t_2 at node 3, where it is picked up by train t_3 and then carried from node 3 to its final destination, node 7. The transfer of a block from one train to another is called a *block swap*. Among the blocks in our example, only b_3 performs a block swap.

Figure 1 shows the interplay between the railroad network, trains, and blocks for a simplified scenario. We have not included the time factor in the figure to keep it simple. In practice, from any station (origin/intermediate/destination) only a limited number of trains can pass through within a specified time window. To avoid congestion, railroads also limit the number of trains passing through any arc of the network. In

addition, the number of cars traveling on any segment must be within a prespecified range. We need to determine the total number of trains and their details (routes, arrival–departure time at each station on the route, frequency, and matching blocks) and honor all these constraints so that the operating cost is minimized. The cost structure may include several factors based on the specific scenario: total distance traveled by cars; total travel time of cars between their O–D pairs; total number of block swaps; total number of locomotives (for pulling the blocks) and crews required; total number of trains formed in a week; total number of train stops at stations; and the variation in block-to-train assignments over a week.

A typical railroad comprises about 400 trains that run on average five days a week, with an average travel time of one day between the O–D pairs. The daily operating cost of a train includes about \$1500 for the locomotive and \$1500 for the crew. Hence, the average annual cost of running one train is approximately \$0.8 million and the average cost of running all trains is around \$320 million. This data suggests that replacing the current manual approach with the OR-tools, in conjunction with improving the service level, will save tens of millions of dollars. We discuss such an optimization model in the next section.

Mathematical Models. The train scheduling problem is a very large scale network optimization problem with trillions of decision variables. Several attempts [12–17] have been made to solve this problem using a two-phase approach, which repetitively develops the train routes followed by the block routes. Some heuristics have also been designed to solve the integrated problem [18] but with limited success. We discuss a decomposition-based two-phase approach, which first determines the train routes and block matching and then decides other details of the train such as frequency and schedule times [2]. Before looking into details of the decomposition approach, we present a simplified mathematical model because the complete global problem is impossible to solve within a reasonable time frame using

current state-of-the-art computing power. We assume that each train runs every day of the week and ignore the train timing.

Let $G(N, A)$ be the scheduling network where N is the set of all origin/destinations/intermediate stations and A is the arc set. We add two dummy nodes s and t , representing the train's global origin and destination, respectively, and an arc (s, t) that denotes the flow of those trains that are not built. It is a variant of the multicommodity flow problem, where each train starting from source s is a unique commodity. We determine if a train $k \in K$ (set of trains) passes through arc $a \in A$ by variable $y_a^k \in \{0, 1\}$; and if it passes, whether block $b \in B$ belongs to the train by variable $x_{ka}^b \in \{0, 1\}$. We aim to minimize the cost of running trains, traveling blocks, and their intermediate swaps (Eq. (8)). As stated earlier, from each station i , the total number of trains originating (T_i^+) or terminating (T_i^-) should be within a limit (Eqs (10) and (11)). Each arc also has a limit (T_a) on the number of trains traveling on it (Eq. (12)). Finally, there are some modeling constraints: flow balance on trains (Eq. (9)), flow balance on blocks (Eq. (13)), and block–train relations (Eq. (14)). The number of cars carried by a train $k \in K$ through arc $a \in A$, should be within the given lower limit L_a^k and upper limit U_a^k . v^b represents the number of cars in a block (Eq. (14)). We assume that the total number of scheduled trains is enough to move all blocks.

$$\begin{aligned} \text{Minimize } & \sum_{k \in K} \sum_{a \in A} f_a^k y_a^k + \sum_{b \in B} \sum_{k \in K} \sum_{a \in A} c_b^k x_{ka}^b \\ & + \sum_{b \in B} \sum_{\substack{i \in N \\ i \neq o(b), i \neq d(b)}} s_i^b \left| \sum_{a \in O(i)} x_{ka}^b - \sum_{a \in I(i)} x_{ka}^b \right| \end{aligned} \quad (8)$$

$$\begin{aligned} \text{subject to } & \sum_{a \in O(i)} y_a^k - \sum_{a \in I(i)} y_a^k \\ & = \begin{cases} 1, & \text{if } i = s \\ 0, & \text{if } i \neq s, t, \forall i \in N, \forall k \in K, \\ -1, & \text{if } i = t \end{cases} \end{aligned} \quad (9)$$

$$\sum_{k \in K} \sum_{a=(s,i)} y_a^k \leq T_i^+, \forall i \in N \quad (10)$$

$$\sum_{k \in K} \sum_{a=(i,t)} y_a^k \leq T_i^-, \forall i \in N \quad (11)$$

$$\sum_{k \in K} y_a^k \leq T_a, \forall a \in A \quad (12)$$

$$\begin{aligned} & \sum_{k \in K} \sum_{a \in O(i)} x_{ka}^b - \sum_{k \in K} \sum_{a \in I(i)} x_{ka}^b \\ & = \begin{cases} 1, & \text{if } i = o(b) \\ 0, & \text{if } i \neq o(b) \text{ or } d(b), \\ & \forall i \in N, \forall b \in B \\ -1, & \text{if } i = d(b) \end{cases} \end{aligned} \quad (13)$$

$$L_a^k y_a^k \leq \sum_{b \in B} v^b x_{ka}^b \leq U_a^k y_a^k, \forall a \in A, \forall k \in K \quad (14)$$

$$y_a^k \in \{0, 1\}, \forall a \in A, \forall k \in K \quad (15)$$

$$x_{ka}^b \in \{0, 1\}, \forall a \in A, \forall k \in K, \forall b \in B. \quad (16)$$

A typical railroad comprises about 2000 stations, 12,000 arcs, 1300 blocks, and 400 trains. In the above simplified model, there are around seven billion X and five million Y binary variables. An instance of this size cannot be solved under current computational capabilities within a reasonable time frame. As we discussed earlier, such problems are solved using decomposition methods. Next, we describe a very effective algorithm to solve the train scheduling problem.

Decomposition Approach to Solve Train Scheduling Problem. The decomposition methods divide the single very large scale problem into several parts and then optimize each part independently using the output of the other parts. We decompose the train scheduling problem in two phases. In the first phase, we determine the routes of each train with its O–D pair and the blocks to be carried, along with optimizing the number of train starts, total train miles traveled, average number of cars per train mile, and the number of block swaps. The algorithm is described in Fig. 2. This second phase uses the solution of the first phase to help determine the other details such as train times and route frequency. It is comparatively more complex and needs more attention.

```

algorithm Train-Scheduling Phase 1;
begin
  Map blocks on the shortest paths;
  for each block destination do
    enumerate all possible trains under the assumption that the train can start only at block's origin;
  while any block  $b$  is not routed
    begin
      Empty the set  $T$ ; //  $T$  is set of trains in which block  $b$  can be attached.
      for each train  $t$  do
        if (O-D pair of the block  $b$  is on the route of any train  $t$  AND a train-path exists for  $b$  from its
          origin to the station to catch the train  $t$ ) then
          determine the goodness of train  $t$  and put it in set  $T$ ;
      create a set of link-disjoint best trains from  $T$ ;
    end;
  for each train  $t$  with per-mile car volume  $< n^{\text{threshold}}$  do // a pre-specified value
    re-initialize the set  $B_t$  with blocks on train  $t$ ;
    if (An alternate route exists for each unassigned block such that
      there are no more than  $k$  trains in the new train path of any of the block of  $B_t$  And
      the new train path should not be more than  $x\%$  of the shortest path) then // a pre-specified value
      delete train  $t$  and reroute its blocks;
  end;

```

Figure 2. Phase 1 of the decomposition algorithm for the train scheduling problem.

The second phase is based on an underlying seven-day train-space-time network, in which nodes represent the physical stops of the train and the arcs represent the train's path. At each of the train stops, additional d nodes are created in time dimension and sorted in the order of departure time to represent the trains running d days per week. *Each train running on a particular day of the seven-day planning horizon is denoted as a train leg.* Once the network is created, this phase is solved in three major steps as explained next. We assume that trains run only by the hour (i.e., at 00, 01, ..., 23 h) and once the departure time is fixed at the origin, then arrival and departure times at other stations can be automatically determined.

- Step 1a: Assume that each train runs every day of the week.
- Step 1b: Add the trains to the time-space network where times have been already specified, and assign the blocks that can be completely routed on these trains.
- Step 1c: Arrange the trains whose times have to be determined in descending order of the total car miles.

Step 1d: Find the departure time of each train in the order sorted by simple enumeration of 24 possible options, and then select the one that minimizes the total car flow time.

Step 2a: Consider the 10 *train legs* with the lowest car volume, and find the impact of the deletion of these legs one at a time.

Step 2b: Delete the train with the lowest impact. Repeat steps 2a and 2b until each train leg has sufficient volume (i.e., each leg contains more than a prespecified number of cars, say 25).

Step 3: Reoptimize the departure times of the remaining trains once again, as detailed in step 1d. This step is required, because while reducing the frequencies of trains in step 2 the block assignment changes. In the new scenario, the previously calculated times (in step 1d) may not remain optimal.

Conclusions. The proposed algorithms have been tested on the real-world data of NS

Corporation [2]. The results achieved were superior in each of the cost terms mentioned earlier in the article, to a varying degree (1–20%). Besides considering all practical constraints of the train scheduling problem, these algorithms are flexible enough to incorporate new business requirements arising at other railroads, such as giving preference to some trains over others and preassigning some blocks to particular trains. These results show the potential for railroads to save millions of dollars by optimizing the number of rolling stocks and the intermediate operations.

The train schedule creates an ideal plan (arrival and departure time at main stations) by routing trains on the given network and assigning blocks to them. However, because of the immense complexity of the problem, it is difficult to factor in all the possible conflicts that could occur as the trains travel and meet along the tracks. We resolve these issues by using the meet-pass planner (train dispatcher), which determines the detailed train movements and timetables.

Train Dispatching Problem

To implement a train schedule in real-life scenarios, it should provide the arrival and departure times of trains not only at the main terminals but also at each track section along their routes. The tracks of a railroad vary from one section to another in their capacities to carry trains. A very simplified track structure is shown in Fig. 3 to describe the relevant terminologies. It contains two major stations (*B* and *D*), two intermediate stations (*A* and *C*) where trains can wait for crossing or overtaking, and four track sections (tracks between two consecutive stations or sidings, e.g., 1, 2, 3, and 4). Sidings are used

for crossing or overtaking. Track section 3 is double-lined, which can allow at most two trains to pass through in any direction; the others are single-lined and can accommodate only one train at a time.

Most of the freight railroads comprise single-line track sections, which causes a delay and deviation from the original plan whenever a train is pulled over to cross or overtake another. The percentage deviation from the original plan is an indicator of deviation from the savings proposed in the section titled “Train Scheduling Problem.” Therefore, in this problem we aim to determine detailed timetables at each track section/sidings (where the trains will meet and pass), which minimizes the total deviation from the original plan honoring several operational and safety constraints. Some of these restrictions are listed below:

- Track capacities should never be violated. It restricts the stoppage of trains at small sidings or intermediate terminals.
- Trains that do not have good traction power to resume moving once stopped at sidings with a sharp slope toward the direction of movement cannot be stopped at those sidings.
- Some trains have extremely strict schedules and incur a very high penalty if they are delayed by more than a prespecified duration.
- Only those intermediate stations that have a well-developed infrastructure to support the needs of crews can be used as a waiting place for long periods.

All of these restrictions make the problem even more complex, thereby limiting the applicability of standard models. We describe

Figure 3. An illustration of track structures.

a mathematical model to show the enormity of the problem, which becomes the basis of IP-based heuristics.

Mathematical Models. The train dispatching problem is a very large scale problem and variants of it have been attempted in literature [19]. Several models have been proposed [20–22] with the assumption that all trains always operate at their constant maximum velocity. These approaches are based on branch and bound techniques [21], Lagrangian relaxation [20], tabu search [22], and other local search heuristics. A few papers [23–26] solve problems with variable trains’ velocity, but with other assumptions such as “only single-line tracks are available,” “traffic flows in only one direction,” or “crossing/overtaking takes place only at stations ignoring the roles of sidings.” All of these simplifications reduce the direct applicability of these approaches in real-world scenarios. In this section, we discuss the algorithm developed by Sahin *et al.* [27], which is based on an underlying space-time network, $G(N, A)$, where N and A denote the nodes and arcs, respectively (Fig. 4). N is the superset of three sets of nodes:

- *Departure Nodes* $D = (d^t)$. Set of artificial nodes each where each element d^t represents the origin of a train $t \in T$.
- *Arrival Nodes* $A = (a^t)$. Set of artificial nodes each where each element a^t represents the destination of a train $t \in T$.
- *Station-Time Nodes* $S = (s^q)$. Set of all pairs of stations/sidings, $R = \{0, 1, \dots, r\}$ and times, $Q = (1, 2, \dots, q)$, equally divided in the given time horizon. Each node (s^q) represents the state of a station/siding $s \in R$ any time $q \in Q$.

Modeling a highly constrained problem as a network flow problem has the intrinsic advantage of reducing the complexity by creating only feasible nodes and arcs. We demonstrate how most of the constraints discussed earlier can be handled while constructing the arc-set A . We create arcs for one train ($t \in T$) at a time following the sequence of origin–intermediate stations–destination,

through which train t passes and the consecutive sections between these stations. While creating these arcs, we assume that railroads comprise only single-line track sections. The network contains four sets of arcs each with unit capacity as follows:

- *Origin Arcs*: Arcs from the nodes of set D to those nodes of set S whose station attribute is the origin (o^t) of the train t ; and the time attribute is between its earliest and latest start times (departure time window of train $tdep^{tw}$). The cost of these arcs corresponds to the length of delays at the starting nodes.
- *Destination Arcs*: Arcs from those nodes of set S whose station attribute is the train’s destination (d^t); and the time attribute is between the corresponding scheduled and latest arrival time (arrival time window of train $tarr^{tw}$) to the nodes of set A . Costs for these arcs are set to 0.
- *Travel Arcs*: Arcs between each pair of nodes of set S whose station attribute represents the pair of consecutive stations on the train’s path; and the time attribute lies within the earliest and latest start time for the section between them. Costs for these arcs are set to 0.
- *Waiting Arcs*: Arcs between each such pair of nodes s^q and s^{q+1} of set S for which the train t is allowed to wait at station/siding $s \in R$ and there is an incoming arc to s^q representing the train’s arrival. If there is an additional constraint that the train t must wait at siding $s \in R$ from time q to $q + 1$, we ignore travel arc from s^q and create only the travel arc from node s^q to node s^{q+1} . Costs for these arcs is set to the length of time period, that is, $q + 1 - q$.

We give the IP formulation based on the space-time network, in which we need to determine the flow x_{ij}^t , of train $t \in T$, on arc $(i, j) \in A$ so that all costs are minimized (Eq. (17)). Constraints (18)–(20), along with the arc-capacity constraints (21), ensure a unit flow of train t from its departure node to arrival node. Constraints (20) maintain the

Figure 4. An illustration of the space-time network for the train dispatching problem.

balanced flow throughout the network. Constraints (22) ensure the flow of at most one train in any section at any time, by enforcing the sum of flows in both directions (T^{out} is outgoing trains from station $s \in R$).

$$\text{Minimize } \sum_{t \in T} \sum_{(i,j) \in A} c_{ij} x_{ij}^t \quad (17)$$

$$\text{subject to } \sum_{q \in \text{dep}^{\text{tw}}} x_{D^t o_q^t}^t = 1 \forall t \in T \quad (18)$$

$$\sum_{q \in \text{arr}^{\text{tw}}} x_{d_q^t A^t}^t = 1 \forall t \in T \quad (19)$$

$$\sum_{i \in S} x_{ij}^t - \sum_{i \in S} x_{ji}^t = 0 \forall t \in T, \forall j \in S \quad (20)$$

$$\sum_t x_{ij}^t \leq 1 \forall (i,j) \in A \quad (21)$$

$$\sum_{t \in T^{out}} \sum_{l \leq q-1} \sum_{m \geq q} x_{s_l(s+1)_m}^t + \sum_{t \in T^{in}} \sum_{l \leq q-1}$$

$$\sum_{m \geq q} x_{(s+1)_l s_m}^t \leq 1 \forall s \in R, \forall q \in Q \quad (22)$$

$$x_{ij}^t \in \{0, 1\} \forall (i,j) \in A, \forall t \in T. \quad (23)$$

A class I railroad generally comprises about 100 stations and sidings, and may require the time interval of 10 min included in the timetable [27]. In this case, a planning period of 48h will result in approximately 28,800 nodes; the flow of even 50 trains will push the number of binary variables up to 720,000. The vast size of the problem

makes the current IP-solvers inapplicable and encourages the development of a heuristic approach. Besides the quality, the solution-generation time should also be low (5–10 min) considering the dynamic behavior of the problem, with continuously changing scenarios depending on the occurrence of several events.

IP-Based Heuristics. The IP-based heuristics is based on two observations from the attempts to solve the IP-model using CPLEX: (i) CPLEX generated optimal solutions for the small-size instances within a few minutes; and (ii) CPLEX generated average quality feasible solution within a minute for large instances. These facts were used by Sahin *et al.* [27] in developing the IP-based heuristics. It is an iterative algorithm, with each iteration solving a smaller-sized problem for a prespecified time. Besides the number of stations, trains, and time windows, the size of the problem in the time-space network depends on how many delays are allowed for each train. A larger delay allowance permits trains to wait at different terminals and increases the number of potential train-paths in the network exponentially. We use only this characteristic to control the size of the problem to be solved in each iteration. The basic framework of the algorithm is given below and other implementation details can be found in Ref. 27. Let *SolutionTime* be the time limit to find the solution.

Step 1: Divide the scheduling horizon q into two periods: short ($q_{\text{short}} \leq q$) and long term ($q_{\text{long}} = q - q_{\text{short}}$).

- Step 2: Initialize allowed delays for each train $t \in T$ by $ad_t = \text{maximum allowed delays}$.
- Step 3: Find a feasible solution by solving the IP-model using CPLEX. Let δ^t be the delay of the train $t \in T$ in the current solution.
- Step 4: Reduce/update the allowed delays for each train $t \in T$. For short term, set $ad_t = \min(\delta^t + \delta^1, ad_t)$, and for long term, set $ad_t = \min(\delta^t + \delta^2, ad_t)$. δ^1 , and δ^2 are incremental changes in train delays.
- Step 5: Find the best feasible solution by solving the IP-model using CPLEX for a prespecified time *IterationTime*.
- Step 6: Repeat steps 4 and 5 until either *SolutionTime* is reached or no improvement is found in step 5.

Conclusions. The heuristics developed to solve the dispatching problems were tested on problem instances of a major Brazilian railroad that transports heavy freight. The resulting plan showed a very large improvement over the railroad's solution by decreasing the deviation from the optimal schedule from 71% to 0.06%. The high solution quality, combined with a fast response time of the algorithm, shows its potential of being developed into a real-life decision making tool.

LOCOMOTIVE PLANNING

After the train schedules have been finalized, the next important problem is to assign a set of locomotives (consist) to each scheduled train so as to provide sufficient power to pull the trains from their origins to destinations at a minimum cost. The schedules of trains differ from one another in several aspects, such as frequency per week, number of days taken to travel from origin to destination, pulling power required, and compatibility with the different types of locomotives. Locomotives also vary in their pulling power, costs, fleet size, fueling and servicing requirements, allowable combination to

form the consist, and so on. Each locomotive must be sent to maintenance shops at periodic intervals (every 3000 miles for regular, and every 10,000 miles for major maintenance) and, therefore, can be assigned only to those trains that do not take them too far from shop locations on their due date. Several other constraints are discussed in the section titled "Mathematical Models," which explains the mathematical model.

These vastly different characteristics of trains and locomotives cause an imbalance in the flow of locomotives on the network, resulting in a shortage at some terminals and a surplus at others. To balance this flow so that the availability of locomotives is ensured for each train, these are either *deadheaded* (pulled like railcars by attaching to a scheduled train) or *light traveled* (traveling on their own without attaching to other locomotives or railcars) from the surplus to shortage terminal. Both of these indicate poor utilization of the locomotives, with light travel also requiring extra crews. Deadheading is less costly than light travel, but it is dependent on the train's schedule and results in comparatively slower travel.

The difference in the power requirement of trains arriving at and departing from a station gives rise to *consist-busting*. Whenever a train arrives at a station, either its consist can be directly assigned to a departing train with same requirement or it can be sent to a pool. At the pool, consists are disassembled and regrouped into new sets of consists comprising different types and numbers of locomotives. Ideally, there should not be any consist-busting, as it is very costly (requires servicing crews and equipment) and is a potential source of delays. If a departing train takes locomotives from several incoming trains, the delay in any of these facets will have a rippling effect in the network (propagating delays all over the network).

A typical railroad has over 3000 locomotives, which translates into a capital investment of over \$5 billion, as well as over \$1 billion in yearly maintenance and operational costs. The locomotive utilization is around 50%. Accordingly, even a small improvement will free up many locomotives (300–400) and

result in a savings of over \$100 million per year.

Mathematical Models

The problem has been studied by several researchers [28–31] with a varying degree of success. Most of them deal with scenarios in which only one locomotive is required for each train, which is applicable only to European railroads. These approaches are not applicable to US railroads where up to 12 locomotives (including both the active and deadhead locomotives) can be assigned to a train. Issues such as the costs associated with deadheading and light travel, as well as the preference between trains and locomotives, are relaxed to keep the problem simpler. Ahuja *et al.* [32] solve the problem including all practical issues, which is further improved by Vaidyanathan *et al.* [33]. The second article is based on consist flow rather than locomotive flow, and thereby nearly eliminates the chances of consist-busting. We will discuss the second approach in this section.

Given a weekly train schedule, we construct a space-time network $G(N, A)$ for the problem and formulate it as a multicommodity flow instance with side constraints, in which each consist type defines a commodity (Fig. 5). The node-set N contains three set of nodes:

- *Arrival Nodes (ArrNodes)*: Each node has the arrival station as its place attribute and the arrival time as its time attributes.
- *Departure Nodes (DepNodes)*: Each node has the departure station as its place attribute and the departure time as its time attribute.
- *Ground Nodes (GrNodes)*: Each node represents a pool at a particular time and station. These nodes facilitate the transition of consists from inbound trains to outbound trains. They are of two subtypes: arrival ground nodes (one for each arrival node with the same place and time attributes) and departure ground nodes (one for each departure node with the same time and place attributes).

We create four set of arcs: $AllArcs = TrArcs \cup CoArcs \cup GrArcs \cup LiArcs$.

- *Train Arcs (TrArcs)*: For each train there is one arc from its *DepNode* to its *ArrNode*.
- *Connection Arcs (CoArcs)*: It contains two subsets of arcs: (i) from each *ArrNode* to its associated arrival ground node, and (ii) from each departure ground node to its associated *DepNode*.
- *Ground Arcs (GrArcs)*: Sort all the *GrNodes* at each station into the chronological order of their time attributes. *GrArcs* connect each ground node to the next ground node in this order. This represents the flow of consist in and out of the pool. These also allow consists to stay in the pool if the outgoing train is not immediately available. The last ground node of the week is connected back to the first node of the week in order to model the fact that the ending inventory of locomotives becomes the starting inventory for the next week.
- *Light Arcs (LiArcs)*: These arcs are from ground nodes of different stations and represent light travel of trains. A fixed cost of light travel is assigned to these arcs.

We now illustrate the mixed integer programming (MIP) formulation based on the space-time network. It should be noted that in this model we deal with the flow of consists rather than of locomotives. We have four sets of decision variables: (i) x_l^c is binary representing if consist type c flows on the *TrArc* l ; (ii) y_l^c denotes the number of nonactive (deadhead, light-traveling, or idling) consist of type c on *AllArc* l ; (iii) z_l is a binary variable to model the existence of any flow of any consist type on *LiArc* l ; and (iv) s^k is the number of unused locomotives of type k .

Railroads have several choices for consists, and they incur different cost (c_l^c based on the compatibility between a consist c and a train l). Most of the locomotive-compatibility-related constraints are resolved by not creating those consists. The objective function

Figure 5. An illustration of the space-time network for locomotive planning.

has four cost terms: (i) total consists cost; (ii) deadhead/light travel/idle cost (d_l^c) of each consist c on any arc l ; (iii) cost of using light arc l (F_l); and (iv) savings (G^k) by not using a locomotive of type k . Constraints (25) ensure that each train is assigned a consist, while constraints (26) and (28) enforce the restriction that a train cannot contain more than 12 locomotives (α^{ck} is the predefined number of locomotives of type k in the consist c) on trains arcs and light arcs, respectively. Constraints (27) maintain a balanced flow through the network, while constraints (29) ensure that the number of locomotives of each fleet type used is no more than the fleet size (B^k). $day(l)$ denotes the number of times an arc l crosses the midnight timeline. For instance, suppose train l leaves at 10 a.m. on day 1 and arrives at 4 a.m. on day 2, then $day(l) = 1$. In contrast, suppose it leaves at 10 a.m. on day 1 and arrives at 4 a.m. on day 3, then $day(l) = 2$.

$$\begin{aligned} \text{Minimize } & \sum_{l \in TrArcs} \sum_{c \in C} c_l^c x_l^c + \sum_{l \in AllArcs} \sum_{c \in C} d_l^c y_l^c + \\ & \sum_{l \in LiArcs} F_l z_l - \sum_{k \in K} G^k s^k \end{aligned} \quad (24)$$

$$\text{subject to } \sum_{c \in C} x_l^c = 1 \forall l \in TrArcs \quad (25)$$

$$\sum_{c \in C} \sum_{k \in K} \alpha^{ck} (x_l^c + y_l^c) \leq 12 \forall l \in TrArcs \quad (26)$$

$$\begin{aligned} \sum_{l \in I(i)} (x_l^c + y_l^c) &= \sum_{l \in O(i)} (x_l^c + y_l^c) \\ \forall i \in AllNodes, c \in C \end{aligned} \quad (27)$$

$$\sum_{k \in K} \sum_{c \in C} \alpha^{ck} y_l^c \leq 12 z_l \forall l \in LiArcs \quad (28)$$

$$\sum_{l \in S} \sum_{c \in C} \alpha^{ck} (x_l^c + y_l^c) day(l) + s^k = B^k \forall k \in K \quad (29)$$

$$x_l^c \in \{0, 1\}, \forall l \in TrArcs, c \in C \quad (30)$$

$$y_l^c \geq 0 \text{ and Integer}, \forall l \in AllArcs, c \in C \quad (31)$$

$$z_l \in \{0, 1\}, \forall l \in LiArcs \quad (32)$$

$$s^k \geq 0, \forall k \in K. \quad (33)$$

The consist-based MIP formulation is smaller in comparison to other locomotive-based models, but the size of the problem still remains quite considerable. A large railroad contains about 600 trains, with each one having a different running frequency, running time, and consist requirement. For the trains that run multiple days, the railroad wants to assign the same consist on each day it runs for the convenience of its operators. Applying these aspects to the MIP will introduce thousands of fixed-charge variables, thereby significantly increasing the complexity and rendering the available software inapplicable. To include all of these issues in the solution model, a decomposition-based heuristics was proposed by Ahuja *et al.* [32]. We briefly discuss it here and refer the readers to Refs 32 and 33 for details. This approach solves the problem in two stages:

- *Daily Locomotive Planning:* We assume that all trains that are running more than a prespecified number of days (p), run every day of the week, and that all trains running less than p days

do not run at all. The space-time network is modified accordingly, and consequently some constraints such as the fleet-size constraints are adjusted. The network size can be decreased by reducing the number of fixed-charge variables. Finally, we use CPLEX to find the solution to the relaxed problem.

- *Weekly Locomotive Planning:* In this stage we adjust the solution of the first stage, which assigns extra consists to some trains (whose frequency increased), and leave selected trains unassigned. A modified space-time network is constructed, in which each train has actual frequency. This stage is solved by further decomposing the multicommodity flow problem into several single-commodity flow problems. We optimize the problem for each commodity (consist type) assuming no change in the assignment of the others. Once all single-commodity problems are solved, a local neighborhood search is applied to improve the solution.

Conclusions

The locomotive planning is a highly combinatorial problem with significant economical impact. As stated earlier, even a minor improvement in the locomotive plan has the potential of saving hundreds of millions of dollars. The proposed algorithm was tested on real-world data from a large North American railroad company, and it showed that the optimized plan schedules all trains with 400 less locomotives than the manual plan. There was also significant improvement in locomotive utilization. These results were obtained by a heuristic approach and they show the opportunities of developing other holistic approaches.

CREW PLANNING

A railroad requires a set of crews that comprise engineers to operate locomotives, conductors to coordinate movement, and other servicing personnel for running the trains. Crew planning involves assigning crews from the set of available crews (*crew*

pool) to trains. The objective is to operate the trains on schedule with a minimum of crew-related costs, while simultaneously satisfying a variety of Federal Railway Administration (FRA) regulations and trade union rules. Besides maintaining the train schedules, railroads also strive to ensure the crew's quality of life (e.g., regular work hours and favorable work locations). However, the FRA and union rules in conjunction with complex train schedules in an overwhelmingly dynamic environment often result in a very complex problem. Accordingly, railroads generally end up using "Assign-Available-Crews-to-Current-Task" rule. Railroads inform crews about their next task just 2h before the train's departure, which can have an origin and destination anywhere in the allowed crew districts. North American rail network is divided into crew districts, each comprising a subset of terminals and rail-links. Each crew is qualified to work only in a subset of crew districts. Crews can be assigned from their current terminal to an *away terminal* where they wait in a hotel until they are assigned back to some other train. *Each crew has a home terminal (generally the home city of the crew members), where railroads do not have to pay for lodging, and all other terminals are called away terminals.* Owing to the imbalanced flow of trains over the network, crews need to be moved by taxi or other trains as idle from the surplus terminal to the shortage terminal. Similar to the terminologies of locomotive planning, we call this idle movement *crew-deadheading*. The deadheading time is counted in normal work hours. Sometimes neither reassigning nor deadheading crews from an away terminal is possible, so they need to wait for a long duration (*crew detention*). If this wait is longer than a prespecified duration (generally 16 h), the crews are paid wages (detention cost) for the extra hours (*total detention hours—16*).

A crew must report for initial preparation before the train's departure, and it must remain to perform some tasks after the train's arrival. The length of time between the arrival (*on-duty time*) and departure (*tie-up time*) of the crew is called the duty period. According to federal law, a train crew must

be sent for sufficient rest (*dead/dog-lawed crew*) depending on the length of their duty period. The crew must wait at least 12 h (10 h of rest followed by a 2-h call period) if the duty period is greater than 10 h, and 10 h (8 h rest followed by 2-h call period) if the duty period is less than 10 h. The minimum 8-h rest period is required after the release from duty, except if no crew is available at the away terminal and either of the following is true: (i) if the recent travel time from the home terminal is followed by a rest of less than 4 h, plus the travel time of a new assignment back home is shorter than 12 h; or (ii) if the recent travel time from the home terminal plus the travel time of a new assignment back home is less than 12 h, and the rest time in between the assignments is more than 4 h. Crews cease doing all duties after consecutive 12 h of work, even if no extra crew is available and the train's departure has to be delayed. A delay also occurs if at any crew change location a crew is not available; this delay costs about \$1000 per hour. There have been some changes in crew's service restrictions as per rail safety improvement act of 2008 which became effective on July 16, 2009, such as (i) 276-h cap on the number of hours operating employee can work in a month; (ii) minimum off duty time has been increased from 8 h to 10 consecutive hours during the previous 24-h period; (iii) the last hour of travel time spent returning from the final trouble call will not be counted toward required off duty time. The complete list of these changes can be found in Ref. 34.

Crews are paid only for their time spent on duty, regardless of the length of their rest period; and they are guaranteed a minimum pay amount per month. The crews are deployed following the first-in-first-out (FIFO) rule at both the home terminal and the away terminals. This guideline requires that the crew with the maximum rest period of all the crews that are resting at the on duty team for the next train is assigned first.

These complex operational, regulatory, and contractual requirements, which also vary from state to state, make it a very challenging problem to solve using mathematical models. Although crew planning

related research has been performed in other industries (e.g., airlines and trucks), in railroads it remains largely unsolved and no commercial optimization product is available for use.

Mathematical Models

Several researchers [35–37] have attempted to solve the crew planning problem using a set-covering based approach. They decompose the problem in *crew pairing* and *crew rostering*. Crew pairing is a sequence of connected segments that not only start and end at the same crew base, but also satisfy all legal constraints. We first find the minimum cost set of the crew pairing so that each segment is covered, and then we use crew rostering to assign individual members to these pairings. A variety of articles solve the problems of different countries such as Hong Kong [38] and New Zealand [28] using heuristics, a localized optimization model, or other IP-based models. In this section, we describe the model proposed by Vaidyanathan *et al.* [39] for US railroads.

We discuss an integer multicommodity flow model with side constraints for crew planning based on an underlying space-time network, $G(N, A)$, as illustrated in Fig. 6. For the sake of simplicity, we show a single crew type of one district and assume that one of the O–D pairs is the home terminal and the rest of the stations are away terminals. It can be easily extended to a general setting. We create four subsets of nodes (N) as follows:

- *Supply Nodes (SupNode)*: One for each crew with time attribute corresponding to the time at which it becomes available for assignment, while the place attribute corresponds to the terminal from which it is released for duty. These nodes have a supply of one unit.
- *Sink Node (SinkNode)*: A common sink node for all crews. Time attribute: end of planning horizon; no space attribute. Its demand equals the total number of supplied crews.
- *Departure Nodes (DepNode)*: One node for each train passing through the crew district. The space attribute is the first

Figure 6. Simplified space-time network for crew planning.

departure station of the train in the crew district, and the time attribute is the on duty time of the train.

- **Arrival Nodes (ArrNode):** One node for each train passing through the crew district. The space attribute is the last arrival station in that crew district, and the time attribute is the tie-up time of the train.

The supply and sink nodes help to ensure the balanced flow of crews in and out of the network. We now create the arc-set, A , as follows:

- **Supply Arcs (SupArc):** Arcs from supply nodes to departure nodes representing the first assignment of a crew to a train.
- **Train Arcs (TrArc):** Each arc connects the *DepNode* and *ArrNode* of a train.
- **Deadhead Arcs (DhArc):** It connects an *ArrNode* or *SupNode* at one location to a *DepNode* at another location. It create only those arcs that satisfy all regulations.

- **Stay-at-Home Arcs (ShArc):** It connects an *ArrNode* or *SupNode* at the home location of a crew to a *DepNode* at the same location.
- **Stay-at-Away Arcs (SaArc):** It is same as *ShArc*, but for at all the away locations of a crew.
- **Demand Arcs (DeArc):** From all *ArrNode* and *SupNode* to the *SinkNode*.

Each arc has an equivalent cost based on its type, such as the crew wage, dead-head cost, or detention cost. All arcs are constructed to satisfy all contractual and regulatory requirements except for the FIFO constraints. The current network does not incorporate train delays caused by the unavailability of qualified crews; however, it can be handled by drawing additional arcs as explained in Vaidyanathan *et al.* [39]. It should be noted that regulations are often crew-pool specific, so on each arc only crews from a specific crew-pools can flow. Therefore, we formulate it as a

multicommodity flow problem in which each crew pool represents a commodity.

We need to find the flow, x_a , on each arc $a \in A$ with the objective (Eq. (34)) of minimizing all crew-related costs as mentioned earlier. Constraints (35) ensure that each train departs with a crew. Constraints (36–38) maintain a balanced flow throughout the network. n denotes the total number of available crew. Constraints (39) take care of FIFO constraints. A_a corresponds to the set of arcs that cannot have a positive flow if there is a flow on arc a . All other notations have been derived from earlier sections.

$$\text{Minimize } \sum_{a \in A} c_a x_a \quad (34)$$

$$\text{subject to } \sum_{a \in O(i)} x_a = 1 \forall i \in \text{DepNode} \quad (35)$$

$$\sum_{a \in O(i)} x_a = 1 \forall i \in \text{SupNode} \quad (36)$$

$$\sum_{a \in I(i)} x_a = n \forall i \in \text{SinkNode} \quad (37)$$

$$\sum_{a \in I(i)} x_a = \sum_{a \in O(i)} x_a \forall i \in \text{DepNode} \cup \text{ArrNode} \quad (38)$$

$$\sum_{a' \in A_a} x'_a \leq M(1 - x_a) \forall a \in A \quad (39)$$

$$x_a \in \{0, 1\}, \forall a \in A. \quad (40)$$

At a typical railroad most crew districts have two terminals, two to four crew types, and about 50 crews. A train schedule has approximately 500 trains running over the course of several weeks in a crew district. In this problem setting, the network has around 1050 ($50 + 2 \times 500$) nodes, 25,000 deadhead arcs, and 100,000 rest arcs. Each rest arc has one FIFO constraint, which makes the problem computationally intractable.

We observe that without FIFO constraints the model reduces to a simple minimum cost flow formulation, and the relaxed problem can be solved up to optimality within 5 s using CPLEX. On the basis of this observation, a two-phase approach has been proposed, whereby the first phase solves the relaxed problem and the second phase handles FIFO constraints in several ways. We suggest a

simple way to consider FIFO constraints and refer our readers to Vaidyanathan *et al.* [39] for other approaches.

Step 1: Solve the relaxed problem and find all FIFO violated constraints. If there are any violated constraints go to step 2, otherwise the current solution is optimal.

Step 2: Add violated FIFO constraints to the model and go back to step 1.

Conclusions

Crew planning is a highly complex problem because of the presence of numerous operational, contractual, and regulatory requirements. A typical railroad employs approximately 20,000 locomotive crews and the other supporting workers receiving a competitive salary. The proposed algorithm has been tested on real-world instances of a major US railroad, and our computational analysis shows a significant benefit in all parameters (crew-caused train delays, crew-deadheading, and crew detentions). The data shows the potential of a reduction in crew-related operating cost by improving the efficiency and effectiveness of the crews that use optimization tools.

SUMMARY

The railroad industry is a very rich source of optimization problems that are of significant economical impact. Numerous complex and conflicting operating rules, external regulations, and other requirements make it overwhelmingly difficult to design the models that can solve real-life instances in a reasonable time frame. We have grouped these intrinsically complex and interrelated problems into three major classes: train planning, locomotive planning, and crew planning. We have discussed the main challenges of each problem and provided some of the most effective solution techniques. The importance of these optimization tools has been shown by a computational study on real-world data, which indicates a total savings of billions of dollars each year.

In this article, we have emphasized the practical approaches to achieve near-optimal solutions, rather than focusing on exact approaches that generate optimal solutions in an unacceptable time frame. This is justified by two key facts: (i) in the highly dynamic real-world, planners generally need to make decisions within a few minutes; and (ii) an excessively large amount of data (input) collected for the optimization model includes some errors. Therefore, even an exact procedure will not generate ideal solutions. The approaches suggested are generic and can be applied to solve other large-scale problems after modifying the models accordingly. There are plenty of opportunities to develop more efficient and effective approaches to further improve the solution quality and response time.

OR/MS APPLIED TO CRICKET

MIKE WRIGHT
Department of Management
Science, Lancaster
University, Lancaster, UK

There has been a steady trickle of academic papers over the past 20 years relating to the application of OR/MS to cricket. There are several reasons for this, including

- cricket's widespread popularity;
- the vast array of strategic and tactical decisions involved in playing cricket;
- cricket's discrete nature that lends itself easily to being modeled;
- the availability of enormous quantities of statistical data relating to professional cricket;
- the large amounts of money involved in professional cricket;
- the growing popularity of betting on cricket;
- the complexity of managing cricket competitions;
- the amenability of cricket timetabling and scheduling problems to OR/MS formulations and solutions.

Moreover, among professional practitioners, the game has recently become much more analytical. It is now commonplace to see not only administrators and managers but also players consulting their laptops in the pavilion during play. At the moment, this is probably mainly used for video analysis of their own play and that of their opponents, but it opens the way for the more widespread practical use of OR/MS implementations before, during, and after a match.

CRICKET'S RANGE AND POPULARITY

Cricket is played across the world, especially in English-speaking countries. Its popularity

is highest in the Indian subcontinent, where it is commonly referred to as a religion. In India, "the country comes to a stop when a cricket match is being played—the roads are deserted, parties and weddings are postponed, operations in hospitals are rescheduled, parliament goes in for early closing" [1]. In Sri Lanka, it was reported that the imminence of a new world record temporarily stopped a war [2].

Cricket is generally regarded as the world's second most popular sport. The number of players in the United Kingdom has been reliably estimated as 3.5 million [3]; with the population of the Indian subcontinent being about 30 times that of the United Kingdom, this suggests that the number of players worldwide must be well over 100 million. The number of professional players in England is about 450 [4]—the worldwide total is probably around 2000.

The number of cricket fans has been reported to be between 2 and 3 billion [5], and the largest TV audience, for the 2007 Twenty20 World Cup Final between India and Pakistan, has been reported variously as 400 million [6] and 1.4 billion [7]. Perhaps most surprisingly, the North American TV figures have been reported to be 37 million [7]—and North America is traditionally indifferent to cricket.

There is no doubt that cricket is of major importance to an enormous number of people and is thus an appropriate area for the serious application of the tools and approaches of OR/MS.

A BRIEF DESCRIPTION OF A CRICKET MATCH

Cricket is a sport played between two teams of 11 players on a large field. At any given time, one team is batting with two batsmen on the field, and the other is fielding with all 11 players on the field. One batsman is the "striker," who stands at one end of the "pitch" (a strip of well-rolled grass, matting, or other material 22 yards long) and receives a delivery (or "ball") bowled by the

“bowler” (one member of the fielding side) from the “nonstriker’s” end of the pitch; the other batsman stands at the nonstriker’s end. A “wicket keeper” stands behind the striker’s stumps and the other nine members of the fielding side are “fielders,” placed anywhere on the field (though there may be some restrictions) by the team captain.

The batsman wields a bat in order to hit the ball and thus score “runs.” When the ball is hit (or even if it is not) the batsmen may choose to attempt to score one or more “runs,” by running from one end of the pitch to the other, as a result of which they may change ends. “Boundaries” may also be scored by hitting the ball out of play—this counts for four runs if the ball hits the ground before going over the boundary, six otherwise.

The fielding side aims to get batsmen “out” along with trying to restrict the scoring of runs. There are 10 distinct ways of getting a batsman out, including “bowled” (where the ball hits one of three vertical pieces of wood known as “stumps”), caught (where the batsman hits the ball and a fielder catches it before it bounces), and “run out” (where the fielder hits the stumps with the ball before the batsman has completed his run). The dismissal of a batsman is known as a “wicket,” or the fall of a wicket. (Cricket terminology can be very confusing to the layman—for example, the pitch is often referred to as the wicket, and the three stumps are also often called wickets.)

Balls are bowled in batches of six (“overs”) by the same bowler, after which a different bowler must be used from the opposite end of the pitch. There may be limits to the number of overs any individual bowler may bowl.

Usually each team just has one “innings” in which they bat, but in some competitions each team has two innings. An innings ends when 10 wickets have fallen, but possibly also after a given number of overs (typically 20, 40, or 50), or after a time limit. In addition, it is allowable and sometimes wise for a team captain to declare his team’s innings “closed” early (see later). The team that scores the most runs wins, except that in some forms of the game a time limit may be overstepped before a result has been reached, in which case the game is a “draw.” If both sides

score the same number of runs, the match is a “tie”—this is quite unusual. A typical number of runs scored in an innings of a professional match may be as low as 100, but is frequently over 500 if there is no overs limit; the record low and high totals are 12 and 1107.

One-innings matches (i.e., where each team has one innings) may take anywhere between two and seven hours. Two-innings matches usually last between three and five days (for “Test” matches between national teams).

For the full laws of cricket, which cover every game of cricket anywhere in the world, see [8]. Every cricket competition also has its own “rules” in addition to the laws. For noncompetitive matches, the team captains agree the rules to be applied concerning, for example, the time or overs limit and any limits applying to individual batsmen or bowlers.

THE CONTRIBUTION OF OR/MS

OR/MS has been used to analyze decision making in cricket at many levels. It has had the most impact at the macro level, addressing issues of importance to the sport’s governing bodies and tournament organizers. However, there have also been several studies of strategic and tactical decision making and it is expected that such studies will have increasing practical influence in future.

The next three sections are therefore organized according to the level at which decisions are taken, starting with the areas where most impact has already been achieved.

DECISIONS FOR ADMINISTRATORS

How to Determine a Winner for a Shortened Match

Often play is deemed impractical or unsafe, usually because of heavy rain, a wet ground, or poor light. This situation is improving as more of the top grounds install improved covers and devices to remove surface water, and more install floodlights, but it is still

frequently impossible to play a match to its natural conclusion.

Often this is unproblematic: the match is declared a draw. However, in some circumstances, it is important that a winner be declared—this is especially the case in knock-out matches, where the winner proceeds to the next round. If there has been a reasonable amount of play, then it may be possible to determine a winner even though the normal winning criteria may not have been met.

Several different methods were originally tried for this, but all led to very unjust outcomes at times. However, two OR analysts devised a system [9] which is now used throughout the world and accepted as being fair by virtually all professionals, though probably few of them understand its intricacies. Given professional cricket's international following, it seems certain that the names of Duckworth and Lewis are far better known than those of any other OR/MS analyst in any field.

The precise details are quite complex, and the model requires calibration using real data, but the main feature of the Duckworth/Lewis method involves the consideration of wickets left and overs remaining as resources; thus, for example, when the number of overs remaining for the side batting second changes because of an interruption, the revised number of runs needed to win depends upon the overall resources available before and after the interruption.

A useful potential by-product of this system is that it can also determine putative winning margins [10] to be used as a tiebreakers for teams with identical win records in a league.

Other methods have been devised [11] which aim to preserve win probabilities. While it is arguable that these may be superior methods, the cricket authorities are very unlikely to consider discarding Duckworth/Lewis.

Fixture Scheduling

For some competitions, scheduling fixtures is easy, using fixed patterns. However, often a more analytical approach is needed using computer algorithms. It may sometimes

be appropriate to use theoretical models [12], but often the situation is too complex for anything other than a custom-built solution.

Sometimes, it must be decided which teams are to play against each other, where, and how often, which can involve issues of fairness [13]. However, it is usually preordained which matches are to be scheduled; just the dates must be decided.

The most extreme case concerns English professional cricket. Eighteen county teams take part in four different competitions—three one-day, one four-day—with different formats. The competitions overlap throughout the season; a team may frequently finish a match in one competition one day and start another match in a different competition the next day.

There are many constraints and objectives; also, the teams have strong preferences that are far from identical for all counties. Travel considerations are important, especially late evening travel, as is the overall pattern of home matches. Teams do not like long gaps between matches; there are matches against touring international teams to fit in; some pairs of teams do not like to have home matches simultaneously; many teams have traditional “festivals,” often at holiday resorts, for which the dates possible are usually very restrictive; often there are also dates to avoid if possible, such as when other sporting fixtures are involved, where the ground is required for a concert, etc.

This problem was successfully approached [14] using a variant that takes advantage of information derived from each separate objective as well as the overall objective.

Other successful implementations have been carried out for the World Cup [15] using a mixture of human decision making and integer programming (see the section titled “Combinatorial Optimization/Integer Programming” in this encyclopedia), for Australian professional cricket [16] using simulated annealing, for New Zealand professional cricket [17] using a mixture of simulated annealing and tree search, and for an amateur league in England [18] using a partly manual heuristic (see the section

titled “Heuristics and Metaheuristics” in this encyclopedia).

Umpire Scheduling

Every match requires two umpires out in the field. For televised matches, there is usually another umpire who analyzes replays of incidents to help the two in the field with difficult decisions. Moreover, for Test matches, there is a fourth umpire mainly acting as a reserve in case another umpire falls ill.

Scheduling these umpires can be difficult. A successful implementation for English professional cricket [19] considered a variety of constraints and objectives and solved the problem using local search, though more recently an improved simulated annealing procedure has been used. Objectives and constraints included journey time, balancing various types of matches, limiting consecutive days worked and spreading umpires out between the teams and each other.

This can also be difficult in amateur leagues; in one implementation [20], an important consideration was the value of one umpire giving a lift to the other, so as to save money on petrol.

STRATEGIC DECISIONS

Strategic decisions so far addressed by OR/MS analysts include team selection, batting order, whether or not to bat first, choosing a “night watchman” and whether and when to declare an innings closed. However, there are plenty of other important decisions that have not yet been studied.

Team Selection

This is an issue about which every fan of any sport has strong views, but very little headway has been made by OR/MS. There have been attempts [21] to devise measures of performance that measure a player’s actual or potential contribution more accurately than those prevalently used, but there is much more work to be done. For example, highly sophisticated techniques have been developed to select football teams [22] and these are widely used among top clubs in the

Netherlands. This is a target that OR/MS analysts could aim at for cricket.

Batting Order

Normally, the best batsmen go in early in a team’s innings and the less able batsmen come in later. This is partly because it is wasteful to have a good batsman stranded if all 10 wickets have fallen, and also because not all batsmen may be needed—this is especially important in games with a low over limit. One study showed how making assumptions for transition probabilities for each batsman separately, any potential order can be simulated [23]; permutations of possible orders were generated using simulated annealing in order to find an order close to optimal.

A batting order does not have to be decided upon at the start of an innings, and a Dynamic Programming (DP) study [24] has shown that captains should make dynamic decisions depending on the state of the game. Another study [25] has considered situations where a day’s play is nearly over when a wicket falls, for a team whose innings will continue the following day. In such circumstances, some captains like to send in a “night watchman,” who is good at defence but poor at scoring runs, to see out the day’s play. This may be useful because any batsman, even a good one, is especially vulnerable at the start of his innings or at the start of a day’s play, and such a batsman would then have to make two “starts.” Some captains do not like to risk this for their good batsmen, whereas other captains think this unimportant and send in their better batsmen ahead of their weaker batsmen in all circumstances. The study’s results came down between these positions, concluding that in some circumstances a night watchman should be used and in other circumstances he should not.

Whether to Bat or Field First

Before the start of every match the captains toss a coin; the winner of the toss decides whether to bat or field first. The captain makes his decision based on factors including the current and predicted future condition

of the weather and the pitch, plus perhaps factors relating to particular players. The toss is regarded as an important part of the game and pundits often put forward opposing views as to the right decision. Where it is not clear-cut, a toss can be regarded as a “good toss to lose,” on the grounds that the captain cannot later be blamed for making the wrong decision.

Regression models [26, 27] have been used to analyze captains’ choices. Results appear to indicate that for one-day matches it is generally better to field first unless the match is due to finish under floodlights, in which case it is preferable to bat first. However, in Test Matches, it appears to be usually advantageous to field first. These results are surprising as most toss winners choose to bat first in all forms of the game.

When to Declare

Where the length of an innings is not limited by a number of overs, but instead there is an overall time limit, a captain may be faced with the decision whether and when to terminate his team’s innings early, or “declare.” The timing of a declaration is often very difficult. Too early and he may be giving the opposition too good a chance of winning. Too late and a draw may be almost inevitable—there will be insufficient incentive for the opposition to take risks, and not enough time for his bowlers to dismiss them.

This has been analyzed using a multinomial logistic regression model [28], and a decision tool has been created with the potential to help second innings declaration decisions in Test matches. Declarations are also possible in a team’s first innings—this again is an important decision but rather more difficult to analyze. Further OR/MS work would be very helpful here.

TACTICAL DECISION MAKING

At all times during his opponent’s innings, a fielding captain must decide where to place the fielders, normally in consultation with the bowler. His decisions are influenced by the prowess of the batsman, the bowler, and the fielders, by the state of the pitch, the weather,

and the state of the game. Professional captains have become more inventive with their field placings recently, making use of video analysis portraying the opposing batsman’s strengths and weaknesses. In tense situations, a captain may make changes every ball, but often the positions remain the same throughout an over.

The bowler decides what kind of ball to attempt to bowl. Variables include ball speed, the location where the ball will bounce (if it does bounce), whether to apply swing, whether to induce lateral movement off the seam of the ball, whether to spin the ball and if so what type of spin—leg-spin, off-spin, googly, top-spin, “doosra,” and possibly others. The more ambitious the intention, the less likely even a top-class bowler is to achieve exactly the desired effect, and most bowlers specialize in particular types of deliveries (e.g., fast swing, slow spin).

The batsman has a split second to react to the ball that is hurtling toward him at up to 100 miles/hour. Not only does he have to decide whether to hit the ball or leave it, the types of shots he can play include the glance, glide, square cut, late cut, upper cut, pull, hook, cow-shot, slog, straight drive, on-drive, off-drive, cover drive, square drive, sweep, reverse sweep, slog sweep, paddle sweep, switch-hit, forward defensive, backward defensive, prod, nudge, nurdle, flick, scoop and possibly others—every now and then, an unexpected new shot is invented. He must also decide how hard to hit it and with what degree of elevation. His decision depends upon the pace, line (direction), length (where it bounces), height of bounce, spin, swing, and so on of the delivery, upon his own strengths and weaknesses, and upon the state of the game—whether he needs to play aggressively or defensively. When he has hit it, or even if he has not, he and his partner need collectively to decide whether to attempt one or more runs.

While there is no time for rational real-time analysis and batsmen react using a mix of reflexes, skill, and experience, there are plentiful opportunities for rational OR/MS interventions in terms of the approach adopted by batsmen. Two examples out of many are discussed below.

Balance between Attack and Defence

One of the most fundamental decisions for a batting team concerns the balance between attack and defence. An aggressive approach will score runs more quickly, but at a greater risk of dismissal. Conversely, with a defensive approach, a batsman may well stay in longer, but his runs will come more slowly.

The optimal balance depends upon the state of the match—the number of overs remaining, the number of batsmen out, and, for the team batting second, the number of runs still needed for victory. (This assumes that the match is of one innings and that there is a fixed limit to the number of overs available. The situation is a little more complex where there is no such limit, especially for two-innings matches, but the same general principles apply.)

This issue has been approached [29] by first creating a model of a limited-overs match, based on stochastic DP. A state of the system is defined by the number of runs required (for the team batting second), the number of wickets lost, and the number of balls remaining to be bowled. Using data from actual matches, probabilities are assumed for the following events: one wicket and no run; neither wicket nor run; one run; two runs; three runs; four runs; and six runs. (This does not quite cover all eventualities: for example, it is possible for runs to be scored and a wicket to fall at the same ball, usually by means of a run out; it is possible to score five or even seven runs; and some deliveries may be “wides” or “no balls,” resulting in an extra run but not counting toward the total number of balls to be bowled. However, it is adequate for the study in question.)

These probabilities vary depending upon the approach taken; under a very aggressive approach, the probability of a wicket is high, the probability of scoring runs is high, and the probability of neither run nor wicket (known in cricket parlance as a “dot ball”) is very low; conversely, with a very defensive approach, the probability of a wicket is low, of scoring runs is low, and of a dot ball is high.

The study calculated the optimal scoring rate to aim for, from any given state of the system, in order to maximize the number of

runs scored for the team batting first, or the probability of victory for the team batting second. The results showed that the prevalent strategy of starting slowly and then speeding up was suboptimal, and that a more aggressive attitude should be adopted right from the start. Subsequent matches have supported this conclusion, and teams now usually show some aggression right from the start.

This analysis has been extended [30] using larger data sets and with variable probabilities—reasonable enough because not all batsmen or bowlers are of equal ability, and probabilities can also vary significantly with pitch and weather conditions. This can be used as a simulator (see the section titled “Simulation Modeling and Analysis” in this encyclopedia) to answer all manner of strategic and tactical questions.

A Strong Batsman Protecting a Weaker One

An intriguing tactical battle often occurs when nine wickets have fallen, if a specialist batsman is accompanied by a much less proficient batsman (probably selected in the team for his bowling). It is up to the good batsman to score runs, as the other batsman is unlikely to score many, and if the weak batsman faces the bowling he has a high probability of being out, leaving the good batsman stranded; even though he is not out himself, the team will have lost 10 wickets and thus the innings ends. So he will aim to face most of the balls bowled.

As the bowling changes ends every over, his ideal is to score an even number of runs from each of the first five balls and an odd number on the sixth ball—generally a single run, as it is very hard to score exactly three runs on purpose. Thus, he would face every ball. However, he cannot guarantee that the runs will come exactly as he wishes; and if he fails to score a single on the final ball, the weak batsman may then have to face all six balls of the next over.

DP analysis [31] has concluded that the strong batsman should normally refuse to take an odd number of runs on the first four balls, but should accept a single run on the fifth or sixth ball, if nine wickets have fallen; otherwise, both batsmen should take every run on offer.

However, this is also a tactical issue for the fielding side. If the strong batsman is on strike at the start of an over, the captain may place the fielders toward the boundary edge, such that it is easy for the batsman to score a single, but very hard for him to run two safely or to pierce the field for a boundary four. He could try to hit the ball over the top of the fielders for a six, but this is often very risky—he could easily be caught out.

This creates a game of “cat and mouse,” where for the first four balls the batsman may hit the ball to a faraway fielder and refuse to run, and for the fifth and sixth balls the captain will bring all the fielders in much closer to minimize the probability of a single. Batsmen may react by accepting a single off the fourth ball, or by trying to hit the ball over the fielders on the fifth or sixth, perhaps happy to accept a boundary four or six as compensation for not being the facing batsman at the start of the next over. The situation could be approached using game theory analysis (see the section titled “Decision and Risk Analysis and Game Theory” in this encyclopedia).

FORECASTING AND BETTING

This is a growing area for study and it is probable that much OR/MS analysis has been undertaken confidentially by betting companies. However, an interesting study [32] has been published using not only regression modeling but also the Duckworth/Lewis analysis. This considered betting during the course of a match, concluding that punters tend to overreact to important events (such as wickets falling).

CONCLUSION

Cricket is a very fruitful area for OR/MS study, with a plethora of decisions to be analyzed, and a fast-growing data bank to help the analysis. Nowadays, for professional matches, a substantial amount of data is recorded for every ball, including field placements, the type of delivery, the type of shot played, and the outcome. Moreover, issues for administrators get ever more complex as new

types of tournament are created. We can look forward to many more papers on the subject.

ORBEL, THE BELGIAN OPERATIONS RESEARCH SOCIETY (SOGESCI-BVWB)

PIERRE L. KUNSCH
Université Libre de Bruxelles,
SMG-CODE Department,
Brussels, Belgium

Vrije Universiteit Brussel, MOSI
Department, Brussels, Belgium

THE BELGIAN OR SOCIETY

SOGESCI-BVWB, the Belgian Operations Research Society, today most commonly called ORBEL, is the Belgian society for the promotion of scientific methods of management. Its goal is to contribute to the diffusion of new tools, methods, and knowledge in the fields of operational research, mathematical programming, statistics, pattern recognition, and related disciplines. It also aims at stimulating research in the above fields as well as developing the cooperation between researchers and with the industry and business, both at national and international levels.

The society today has about 120 members. It represents Belgium in a number of international associations and federations of national societies including

- EURO, the European Association of Operational Research Societies;
- IFORS, the International Federation of Operational Research Societies.

SOGESCI-BVWB also coedits the journal 4OR: a quarterly journal in operations research published by Springer, along with the French and Italian OR societies.

The SOGESCI-BVWB website is at www.orbel.be.

HISTORY

SOGESCI-BVWB started as a Belgian nonprofit organization in today's form in January 1962, as a merger between the "Belgian Society for the Industrial Application of Statistics" (ABSI) founded in Brussels in 1957 and the "Belgian Association for the Application of Scientific Methods of Management" (AGESCI) founded in Brussels in 1958. Starting with the mergers of two associations founded in 1957–1958, SOGESCI-BVWB may claim over 50 years of existence.

Belgium being a trilingual country with French and Dutch as the two main languages, the new society needed a composite name.

SOGESCI is the French acronym for "Société Belge pour l'application des Méthodes Scientifiques de Gestion ASBL," while BVWB is the Dutch acronym for "Belgische Vereniging Voor de Toepassing van Wetenschappelijke Methoden in het Bedrijfsbeheer." No official German acronym was provided.

To make things easier it has been—unofficially—decided for some years to use the name of the annual national conference name of ORBEL, standing for "Operations Research in Belgium," as a convenient acronym for common use between members.

The list of past presidents going back to 1980 from today is as follows:

F. Broeckx 1980–1984
J. Teghem 1984–1986
M. Despontin 1986–1988
Ph. Vincke 1988–1990
H. Pastijn 1990–1992
M. Roubens 1992–1994
F. Broeckx 1994–1996
M. Pirlot 1996–1998
D. Cattrysse 1998–2000
P. Kunsch 2000–2002
F. Plastria 2002–2004

E. Loute 2004–2006
 G. Janssens 2006–2008
 R. Bisdorff 2008–2010
 P. De Causmaecker 2010–2012

Several members of SOGESCI-BVWB are very active in EURO and IFORS and they have occupied important positions therein, such as the following:

Jean-Pierre Brans, former professor at Vrije Universiteit Brussel (VUB), and SOGESCI-BVWB president 1974–1976, has been a cofounder of EURO, organizing the first EURO I conference in Brussels in 1975. He was president of EURO in 1983–1984, and received the EURO Gold Medal in 1994. He was also IFORS vice president in 1977–1980 and 1989–1992.

Philippe Vincke, Professor at Université Libre de Bruxelles (ULB), its rector in 2006–2012, and SOGESCI-BVWB president 1988–1990, was EURO president in 2001–2002.

Martine Labbé, Professor at ULB, was EURO president 2007–2008.

Jacques Teghem, professor at Faculté Polytechnique de Mons (FPMs), and SOGESCI-BVWB president 1984–1986, was editor of EJOR, the European Journal of Operational Research of EURO till 2007.

Raymond Bisdorff professor at Luxembourg University, and SOGESCI-BVWB president 2008–2010, was EURO vice president in 1998–2000. Note that, for the first time in the history of ORBEL, a non-Belgian citizen was elected for the ORBEL presidency due to the very close links between OR researchers in Luxemburg and Belgium.

ORGANIZATION

The Board of Administration gathers all administrators of SOGESCI-BVWB. Each mandate is renewed every two years.

The Executive Committee emanating from the Executive Committee consists of the president, the three last past presidents acting

as vice presidents, the president-elect, the treasurer, the secretary, the delegate administrator, the webmaster, and administrators responsible for the newsletters, or for the organization of the ORBEL activities.

The meetings of the General Assembly usually take place at the occasion of the annual ORBEL conference.

Meetings of the executive committee and of the board of administration take place at the headquarters of SOGESCI-BVWB located at the Royal Military Academy (RMA) in Brussels. All meetings are held in English to simplify administrative matters. English is also the official language of the annual ORBEL conference.

The RMA has traditionally hosted in its premises, the annual national conference ORBEL, which was biannual till 1990; it is organized by an academic chairperson, the post being a rotating one. For many years now, the annual, typically two-day, ORBEL conference takes place alternately in a French-speaking or Dutch-speaking university in the country. The 50th anniversary of SOGESCI-BVWB was celebrated in January 2008 at RMA at the occasion of the 22nd ORBEL conference. Some speakers from the early days of the society were invited for delivering talks about the history of our society.

SERVICES TO MEMBERS

The Society offers members a number of services to its member including the following ones:

- free subscription to the journal 4OR;
- organization of annual conferences and workshops;
- awarding of the SOGESCI-BVWB master's thesis award;
- an email newsletter about OR-related calls for papers, jobs, books, seminars, and conferences.

There are privileged links to many other national societies which are members of EURO, such as

- Italian Association for Operations Research (AIRO), Italy;

- Australian Society for Operations Research (ASOR), Australia;
- German Operations Research (GOR) Society, Germany;
- Danish Operations Research Society (DORS), Denmark;
- French Society of Operations Research and Decision Support (ROADEF), France;
- Nederlands Genootschap van Besliskunde (NGB), The Netherlands;
- Institute for Operations Research and the Management Sciences (INFORMS), United States;
- Operations Research Society (ORS), United Kingdom.

Furthermore, there are links to the Belgian Statistical Society (BSS), the Belgian Engineers Societies FABI (French speaking), and KVIV (Dutch speaking).

THE ORBEL AWARD

The ORBEL award, organized by ORBEL, is bestowed on the author(s) of a scientifically oriented master's thesis.

The criterion for judgment is the appropriateness of the scientific approach applied to solve the problem under study. The author(s) should emphasize the application of existing methods in new areas or the application of new methods of dealing with models recognized as useful for solving real-life management problems. Therefore, actual collaboration with industry during the thesis elaboration is one of the selection criteria.

Examples of recently awarded master theses are as follows:

- Measures of congestion in container terminals.
- Matrix approximation and under approximation by nonnegative factorization: algorithms, complexity and applications.
- A discrete-time queueing model with batch service.
- Fire station location models and applications in Belgium.

CONFERENCES AND WORKSHOPS

Although the big majority of ORBEL members are academics, very many efforts have been made to attract more and more practitioners from the industry, especially for the annual conferences or topical workshops. These scientific events are understood by our society as being meeting places between academia and industry.

ORBEL conferences are organized every year, in January, and bring together most of the people concerned with OR and quantitative techniques for decision making in Belgium; they also attract a number of specialists from the neighboring countries.

Young researchers and PhD students are invited to attend the ORBEL conference at a reduced registration fee which also includes a one-year membership to SOGESCI-BVWB.

The ORBEL conferences consist of invited lectures delivered by prominent foreign specialists and practitioners on topics of general interest; more specialized contributed papers are presented in parallel sessions by young researchers.

The winner of the ORBEL award for the best Master's thesis in OR is also announced at the conference and the student is invited to present his/her work there.

The last 23rd ORBEL conference took place at Leuven University (KUL) in 2009 with more than 120 participants. ORBEL 24 will take place at Université de Liège (ULg) in 2010.

Workshops on a particular theme are also organized. These one-day meetings are devoted to a single topic; the invited lectures are selected in order to provide an overview of recent and important developments in some fields of interest.

In recent years, workshops have been devoted to discrete-event simulation, fuzzy logic and constraint programming, data mining and operations research, current research in location theory, and optimization in engineering.

THE 4OR JOURNAL

The journal "4OR, A Quarterly Journal of Operations Research" started in 2003. This

refereed joint journal of the three national OR societies of Belgium, France, and Italy is offered free to all their members. It is published by Springer, and available on-line. It will be listed by the ISI, starting from 2010. Professor F. Plastria of the Vrije Universiteit Brussel, a former ORBEL president, has been editor-in-chief representing the Belgian society from the beginning till the end of 2009.

The former journal JORBEL stopped after the last volume 41 (2001). This refereed quarterly journal published scientific contributions; special issues were devoted to

particular topics and contained a review or tutorial paper. The most recent special issues were centered around general heuristics, production management, and constraint programming; a collection of tutorial lectures presented at the Francophone Operations Research (FRANCORO) conference in 1996 also appeared.

The Borsalino project aimed at having the complete archives of JORBEL freely available on-line. It is now completed, and all articles from the journal are today available from the ORBEL website www.orbel.be.

ORSP: FORGING AHEAD IN ITS TWENTY-FIFTH YEAR

ELISE DEL ROSARIO

Formation of the national OR Society of the Philippines (ORSP) was an initiative of the private sector with the full support of the academe. The San Miguel Corporation's Operations Research Department (awarded the 1992 ORSA prize for consistent and sustained OR/MS support to decision making at all levels of the organization) hosted a dinner dubbed "A Toast to OR Professionals" in December 1986. This led to a frenzy of activities that culminated in the official recognition of the ORSP in February 1987.

The very first symposium of this organization that featured OR applications in various sectors metamorphosed into quarterly technical forums on issues such as traffic, agriculture, environment, energy, business logistics, health, sustainable development, and finance. Regular workshops on the use of spreadsheets and various simulation software were held. Its annual general membership meeting coincides with the annual national conference in which professionals from all over the country discuss directions for the society, present their technical papers, and get updated on local and international OR developments.

ORSP became a member of the International Federation of Operational Research Societies (IFORS) in 1990. In 2007, one of its founders, Elise del Rosario, assumed the presidency of the international body. ORSP organized its first international conference, the 1990 International Conference on OR/MS (ICORMS) in the same year in which the first issue of the *Philippine Journal of Operations Research* appeared (currently published online in its web site, www.orsp.org.ph; the *ORSP Newsletter* is also available in this web site). In 1997, ORSP hosted the second ICORMS jointly with the IFORS' annual International Conference on OR in Development (ICORD), followed in 2004 by the

IFORS Workshop for Teachers in Developing Countries. In 2006, ORSP hosted the Association of Asia Pacific OR Societies (APORS) seventh conference. In this meeting, Philippine President Gloria Arroyo acknowledged the contribution of OR in development and challenged ORSP to help the government in some of its programs.

At this time, the ORSP Committee on OR for Public Service (ORSP Corps) had been well established. With a mission to help in nation building through the use of OR, the committee has helped government agencies such as Philippine Ports Authority, Bureau of Customs, Commission on Elections, and National Power Corporation since 1999. Before this, the organization had links with the Department of Science and Technology, which sponsored its forums on public sector applications, and had two Philippine presidents grace its Annual General Membership meetings.

ORSP does not lose sight of the future OR professionals: the students. Early on, ORSP laid down the foundation for the formation of student chapters and inducted its first one in 1989. It has since accredited 19, who comprise the ORSP Federation of Student Chapters. The Federation actively sponsors get-togethers, and an annual student congress, lectures, interuniversity OR quiz, and paper writing contest.

It can indeed be concluded that since its founding in 1987, ORSP has remained at the forefront of promoting the advancement and practice of OR in the Philippines for 25 years.

Table 1 shows that ORSP has seen 14 presidents in the 25 years it has been in existence. The president is joined by 10 board directors including a vice president, secretary, and treasurer, who are elected for a term of two years with a maximum two-term limit.

Table 1. The ORSP Presidents

Year	ORSP President
1987–1988	William Torres
1988–1990	Elise del Rosario
1990–1992	Felipe Fondevilla
1992–1994	Manuel Agustin
1994–1996	Olegario Villoria Jr
1996	Elvira Zamora
1997–1998	Aura Matias
1998–1999	Emmanuel Macalalag
1999–2000	Wilson Wy Tiu
2000–2002	JC Mercado
2002–2004	Vicente Reventar
2004–2006	Elise del Rosario
2006–2008	Alleli Domingo
2008–2010	Alleli Domingo

OVERWEIGHTING OF SMALL PROBABILITIES

ZACH BURNS

ANDREW CHIU

GEORGE WU

University of Chicago Booth School of
Business, Center for Decision
Research, Chicago, Illinois

Consider the decisions of whether or not to undergo heart surgery, evacuate a city when a tropical storm is approaching, or increase counterterrorist measures. These decisions involve consideration of both the likelihood and the impact of surgical death, a Category 3 hurricane, or a September 11-magnitude terrorist attack, respectively. Assessing the likelihood of these events is difficult, with experts often disagreeing on the chance that the relevant event will occur [1]. Rare events are also important when they involve extreme consequences, whether good or bad. Indeed, much of risk and policy analysis is devoted to the study of low probability, high consequence events, such as a nuclear accident or a terrorist attack [2].

Research in judgment and decision making suggests that decision makers do not weight rare events according to their actuarial chances of occurring. Instead, small probability events tend to be overweighted for two reasons: (i) decision makers tend to overestimate the chance that rare events will occur; and (ii) small probabilities are overweighted in terms of their impact on decisions. Combined, these two pieces suggest that rare events are given greater psychological weight in our minds than is normatively appropriate.

Although both parts contribute to the overweighting of small probability events, it is nevertheless important to distinguish between these two separate processes. Events with a low probability of occurring may be overestimated, or perceived as more likely than they actually are. For

example, someone considering a move to San Francisco may overestimate the probability that the Bay Area will suffer from an earthquake in the next 5 years. However, small probability events can loom large in decisions, even when these events are not overestimated. For example, consumers find lottery tickets attractive, even though they may be very much aware of the low chances of winning [3,4]. In this article, we review empirical findings from judgment and decision making research that illustrate how these two stages contribute to the overweighting of small probability events.

A TWO-STAGE FRAMEWORK

In the classical theory of decision under uncertainty, subjective expected utility theory, the utility of each outcome is weighted by the decision maker's subjective probability that this outcome will obtain [5,6]. Consider a prospect, $A = (E_1, x_1; \dots; E_i, x_i; \dots; E_n, x_n)$, that offers outcome x_i if event E_i occurs, where events E_i are mutually exclusive and collectively exhaustive. Subjective expected utility evaluates the prospect A as follows,

$$U(A) = \sum_{i=1}^n P(E_i)u(x_i),$$

where the utility function, $u(x_i)$, measures the value the decision maker attaches to outcome x_i , and the subjective probabilities, $P(E_i)$, capture the decision maker's assessment of the likelihood of event E_i and satisfy the basic axioms of probability.

Although subjective expected utility is a standard building block for economic analysis [7], a large number of experimental studies have found that people are inconsistent with this model: subjective probability judgments violate the basic axioms of probability [8], and preferences are inconsistent with the axioms

underlying expected utility theory [9,10]. Of the numerous alternative models that have been proposed [11], prospect theory is consistent with the broadest set of empirical observations critiquing expected utility theory, such as the common-consequence effect (e.g., the Allais Paradox), the common-ratio effect, the fourfold pattern of risk preferences, and the simultaneous attraction of lottery tickets and insurance (see *Prospect Theory and Paradoxes and Violations of Normative Decision Theory*) [3,10,11]. Prospect theory uses a probability weighting function, $\pi(p)$, to capture the distortion of probabilities (see *Probability Weighting Functions*), and a value function, $v(x)$, to account for the evaluation of outcomes.

We extend prospect theory using a two-stage framework proposed by Tversky and Fox [12,13]. Consider a prospect that offers \$100 if a thumbtack is flipped point down three times in a row (and \$0 otherwise). The two-stage process suggests that the weight assigned to the outcome \$100 reflects: (i) a decision maker's *subjective probability* that a thumbtack will be flipped point down three consecutive times; and (ii) a distortion of the subjective probability that captures the impact of that probability on the attractiveness of the prospect. This framework allows for bias at each of the two stages. More formally, consider a prospect that pays x if event E occurs (and 0 otherwise), denoted (E, x) for simplicity. The weight assigned to outcome x is $W(E) = \pi(P(E))$, where $P(E)$ captures stage 1 (the judgment of the likelihood of E) and $\pi(P(E))$ captures stage 2 (the distortion of $P(E)$) as measured by $\pi(p)$, the probability weighting function. Overestimation of rare events occurs if $P(E)$, the judged likelihood of event E , is higher than the actuarial probability of E , whereas overweighting of probability occurs if $\pi(P(E)) > P(E)$.

In the section titled "Stage 1: Overestimation of Rare Events," we discuss overestimation in likelihood judgments, and identify some psychological factors that contribute to this phenomenon. We then discuss overweighting in decisions involving small probabilities in the section titled "Stage 2: Overweighting of Small Probabilities in Decision Making."

STAGE 1: OVERESTIMATION OF RARE EVENTS

Overestimation

Mortality risks have been commonly used to examine the perception of low probability events. During the last three decades, a number of studies have shown that participants consistently overestimate the risks of death due to low probability causes, while underestimating risks of death from high probability causes [14–16]. Consider a classic study conducted by Lichtenstein and colleagues, where participants judged the frequency of lethal events in the United States. Lichtenstein *et al.* compared the judged estimates to the actual death rates and found that low frequency events (such as smallpox, poisoning by vitamins, and botulism) were overestimated by a factor of 10, while high frequency events (such as stomach cancer, stroke, and heart disease) were underestimated [17].

In the next three sections, we sketch three psychological mechanisms that drive overestimation of rare events. Our account of mechanisms is by no means comprehensive; the literature contains a number of other often complementary psychological accounts [18–20]. In addition, the overestimation described in this section is not universal. For example, because rare events are not always experienced, they are actually underestimated in some cases as a result [21]. Of course, when rare events are actually experienced, they tend to be overestimated, independent of the psychological mechanisms described below [22].

Availability

Tversky and Kahneman proposed that people deal with the cognitively difficult task of assigning probabilities by using simplifying heuristics [23]. If you are asked to estimate the divorce rate in your state, you may mentally work through your list of friends, and tally how many of these friends have been divorced (or may likely to become so soon). This example illustrates the *availability heuristic*, whereby judged likelihood is based on the ease with which relevant instances

come to mind. Although this heuristic often produces quite sensible probability estimates, in some cases it may lead to systematic biases. For example, two people with the same number of divorced friends may nevertheless judge the divorce rate differently. The availability heuristic suggests that a person whose best friends are divorced will tend to overestimate this rate compared to the person whose best friends are married.

Tversky and Kahneman provided a clear empirical demonstration of this heuristic [24]. One group of participants estimated the proportion of words in a typical English text with the letter “n” in the penultimate position. Another group estimated the proportion of words ending in “-ing.” Although the former must be larger than the latter, participants overwhelmingly judged “-ing” words to be more common than “-n-” words. This is because it is much easier to recruit examples of “-ing” words than “-n-” words. In essence, “-ing” words . . . , “-ing” words are more psychologically available.

We suggest that the availability heuristic will generally give rise to the overestimation of small probability events. The most important low probability events involve extreme consequences, such as plane crashes or winning the lottery [2]. These events tend to be discussed disproportionately and are psychologically more salient, at least in part because high impact events receive media coverage disproportionate to the actual rate of occurrence. For example, Combs and Slovic found that newspapers tend to over-report deaths by homicides, accidents, and natural disasters, and under-report deaths from disease relative to their frequency [25]. In addition, accidents tend to be more dramatic and emotionally evocative, and thus, easier to recall [17,26].

Anchoring on the “ignorance prior”

The French mathematician Laplace proposed a principle that has become known as the *principle of insufficient reason* [27]. Suppose someone is asked to provide probabilities that each of the 16 baseball teams in the American League will advance to the World Series. A non-American who is completely unfamiliar with baseball may lack a compelling reason

to judge one team more likely to win than any other, and thus may conclude that each of the 16 teams has an equal chance (1/16) of winning the American League division. Of course, in many situations, individuals have some knowledge to use for making probabilistic judgments. Nevertheless, recent research has suggested that individuals often start by assigning equal probabilities to each of the possible events (the “ignorance prior”) and then make insufficient adjustment to each of these probabilities [28,29]. We suggest that this process will often result in overestimation of small probabilities.

We first present evidence that decision makers anchor on the ignorance prior. One implication of this process is partition-dependence, in which dramatically different probability estimates are produced, depending on how the event space is partitioned. Fox and Clemen asked Duke MBA students to estimate the likelihood the salary of a random MBA student would fall in each of several salary brackets [28]. In the low condition, there were four salary brackets below the median income of \$85,000, and one above. In contrast, the high condition had one bracket below the median and four above that value. Overall, participants in the low condition estimated that there was a 75% chance that a student would earn less than \$85,000, compared to 40% in the high condition. As predicted, these probabilities are close to the ignorance prior of 80% for the low condition and 20% for the high condition.

Anchoring and adjustment is a process in which decision makers start by “anchoring” on a particular quantity—even if this number is arbitrary or unrelated to the problem at hand—and then adjust insufficiently away from the anchor [23]. Of course, in many situations the anchoring step is well-justified. For example, this year’s sales is usually a good starting point for estimating next year’s sales. However, the anchoring and adjustment process often leads to systematic biases. In one demonstration, Kahneman and Tversky asked participants to estimate the percentage of African countries in the United Nations. In the first stage, a wheel was spun with equal chance of it landing on numbers 0 to 100. Participants were then asked

whether the actual percentage was higher or lower than the number on the wheel. In the second stage, participants were asked to estimate the actual probability. The correlation between the number spun and the eventual estimate was very high, even though it was clear to participants that the number was randomly generated, and had no informational value for the estimate at hand.

Anchoring and adjustment from the ignorance prior thus leads to overestimation of rare events when the number of events in the partition is not large. In most cases, the partition of events includes a small number of events, such as 2 (e.g., “bags will be lost in transport” or “bags will not be lost in transport”) or 3 (e.g., “the Pittsburgh Steelers win,” “the Pittsburgh Steelers lose,” or “the Pittsburgh Steelers tie”). Thus, rare events will be overestimated if a decision maker begins by assigning each event a $1/n$ chance, where n is the number of events in the partition, and then adjusts insufficiently toward the “true probability.”

Coarse Chance Categories

A classic study by Piaget and Inhelder found that the typical 4-year-old child divides chance events into three categories, “certainly will happen,” “certainly will not happen,” and “will possibly happen” [30]. Adults often act as if their categorization of the event space is similarly coarse. For example, Fischhoff and Bruine de Bruin found that participants provided a disproportionate number of probability judgments of 50%, even for mortality-related risks from smoking-induced lung cancer and breast cancer (which are relatively small probabilities in the overall population), indicating equal probabilities of “will occur” and “will not occur” [31]. At the other extreme, professional weather forecasts and expert bridge players are relatively well-calibrated (i.e., events which they judge to have a 20% chance of occurring actually occur 20% of the time), partly because these experts have a finer categorization of the probability interval [32,33].

By definition, low probability events are encountered infrequently, and thus, individuals do not have very much practice thinking about such events. Reyna and

Brainerd suggest that people understand probabilities in “gists,” meaning that they form a general impression rather than a precise probability of whether an event will occur [19]. In this way, it is likely that people form broad notions of probabilities in coarse categories instead of a specific number. Put differently, people seem to differentiate *across* chance categories, but not *within* [34]. Indeed, people prefer communicating probabilistic information verbally rather than numerically, even though verbal statements are less precise [35]. As a result, rare events are lumped into a single category of “unlikely” outcomes. To the extent that “unlikely” corresponds to probabilities between 0.15 and 0.20 [36], this coarse categorization process will lead decision makers to overestimate rare events.

STAGE 2: OVERWEIGHTING OF SMALL PROBABILITIES IN DECISION MAKING

Prospect Theory

We next turn to evidence that small probabilities are overweighted in decision making. Research leading up to the development of prospect theory showed that individuals do not weight probabilities linearly, as would be predicted by expected utility theory. Like expected utility theory, prospect theory assumes that individuals evaluate each alternative and then choose the alternative with the highest subjective valuation. Prospect theory also assumes that the decision maker values the possible outcomes, the probabilities of obtaining those outcomes, and then combines those valuations together. The major difference between prospect theory and the classical theory is that the valuation of outcomes is governed by the value function, $v(x)$, while the valuation of the probabilities is governed by the probability weighting function, $\pi(p)$. The value function is S-shaped, concave for gains and convex for loss, and steeper for losses than gains (see *Prospect Theory*). The second component, the probability weighting function, is the piece of prospect theory that captures the psychological phenomenon of overweighting of small probabilities.

Figure 1. A typical prospect theory probability weighting function, $\pi(p)$, which is concave for small probabilities and convex for medium to large probabilities (and thus, consistent with the principle of diminishing sensitivity).

We should note that small probabilities are not always overweighted. On the contrary, they may be ignored if the probability is below some threshold [37].

Psychophysics of the Probability Weighting Function

Prospect theory assumes that individuals do not weigh outcomes by their probability, as in expected utility theory, but by some distortion of probabilities. This distortion of probability is captured by prospect theory's probability weighting function, $\pi(p)$. The main psychological principle governing the distortion of probability is *diminishing sensitivity* away from a reference point. For probability, there are two obvious reference points, impossibility and certainty, or 0% chance and 100% chance. The distortion of probability captured by the probability weighting function captures the diminishing sensitivity away from these two reference points. People are most sensitive to changes in probability when they are near 0% or 100% than when the change applies to intermediate probabilities. Thus, most people regard the change from 0% to 1% as significant, because it changes the chance of winning from impossible to possible, a phenomenon known as the *possibility effect*. In addition, improving a 99% chance at winning by 1% is also

substantial, because the chance of winning has shifted from almost certain to certain, a phenomenon known as the *certainty effect*. In contrast, a chance from 32% to 33% is seen as inconsequential. Algebraically, both $\pi(0.01) - \pi(0)$ and $\pi(1) - \pi(0.99)$ are larger than $\pi(0.33) - \pi(0.32)$. More generally, a typical probability weighting function is concave for low probabilities and convex for medium to high probabilities (see Fig. 1).

Tversky and Kahneman conducted a study that illustrates this nonlinearity [10]. Participants provided certainty equivalents for gambles that provided 5, 50, and 95% chances at winning \$100 [10]. They found that the certainty equivalents for these gambles were \$14, \$36, and \$78, respectively. The first 5% contributes \$14 of value (or \$2.80 for each percentage), while the next 45% is only worth \$22 (or \$0.48 for each percentage). The final 5% adds \$22 in value (or \$4.40 for each percentage), compared to the previous 45%, which contributes \$42 (or \$0.93 for each percentage).

Diminishing sensitivity implies that low probabilities are typically given more weight than they would receive using expected utility. Empirically, there is generally overweighting, $\pi(p) > p$, for $p < 0.35$ [38,39]. This overweighting, combined with an S-shaped value function, is consistent with

risk-seeking for low probability gains (such as lottery tickets) and risk-aversion for low probability losses (such as insurance). (Note, however, that overweighting of probabilities is distinct from risk-seeking. For gains, concavity of the probability weighting function for low probabilities “competes” again with concavity of the value function. Thus, risk-seeking is observed for probabilities around 0.10 or less [10].) Medium to high probabilities are typically given less weight than they would receive using expected value. Such underweighting is consistent with risk-aversion for medium to high probability gains, and risk-seeking for medium to high probability losses.

Affect and Risk

The shape of the probability weighting function also depends on the affective reactions associated with potential outcomes of a risky choice. Affect is the psychological concept that encompasses noncognitive reactions to stimuli, such as arousal, emotions, or moods. Some outcomes are relatively affect-rich, while others are relatively affect-poor. In a set of studies, the probability weighting function was more curved for affect-rich targets (such as kisses and electric shocks) than affect-poor targets (such as money) [40]. In particular, Rottenstreich and Hsee demonstrated a preference reversal in which participants preferred \$50 in cash to “the opportunity to meet and kiss your favorite movie star,” but chose a 1% chance at a kiss over a 1% chance at \$50. This study suggests that there is more overweighting of small probabilities for affect-rich outcomes than affect-poor outcomes.

The affective account is compelling because many of the risks that are overweighted in judgment are dramatic, fear-inducing and catastrophic, and hence affect-rich. While rare events that are affect-poor in nature may also be overweighted, events that are affect-rich are likely to be overweighted to a larger extent. In the aftermath of the attacks on 9/11, Vice President Dick Cheney set out what has become known as the *One Percent Doctrine*: “We have to deal with this new type of threat in a way we have not yet defined...With a low-probability,

high-impact event like this...if there is a 1% chance that Pakistani scientists are helping al Qaeda to build or develop a nuclear weapon, we have to treat it as a certainty in terms of our response” [41]. The One Percent Doctrine is an extreme example of overweighting of small probabilities, but less extreme risks are typically overweighted as well, although to a lesser extent.

SUMMARY

The overweighting of small probability events is the result of a two-stage process. In the first stage of overestimation of rare events, decision makers take information they receive from the world and then recruit from their memory and convert that information into a psychological representation of probability. As such, this stage is particularly susceptible to many of the basic cognitive limitations and shortcuts identified by psychological research, biasing the resulting judgments in a predictable manner. Though by no means an exhaustive list, we have identified several of the most important, including the availability heuristic, anchoring on the “ignorance prior,” and coarse chance categories. In the second stage of overweighting of small probability events, these (perhaps already inflated) probabilities are distorted upward due to the psychophysics of chance and affect.

Although eliminating these biases altogether is probably unrealistic, it is nevertheless possible to reduce these biases. Many of the most effective approaches will require identifying and then addressing the particular psychological mechanism that produced the biased probability judgment [42]. Consider, for example, the availability heuristic. To the extent that salient and vivid instances tend to come to mind and are thus overweighted in a decision, organizations might force decision makers to rely on historical actuarial evidence rather than what evidence they would naturally recall. Alternatively, organizations may develop “cognitive repairs” [43]. For example, a division at Motorola was overly focused on the problems of large customers, even though small customers constituted a large revenue

base for the division. Motorola developed a process in which problems were surveyed more systematically and weighted by customer volume. In contrast, anchoring on the ignorance prior requires a different intervention, such as a thoughtful consideration of how to partition the space of events [28].

In the second stage, small probability events are additional inflated, as captured by the probability weighting function. Fortunately, this bias is easily addressed when decisions are made using the standard analytical methods of decision analysis [44]. In decision analysis, outcomes (or the utility of these outcomes) are multiplied by their probability of occurring, with the alternative with the highest expected value (or expected utility) being selected.

Traditional economic decision theory proposes that people behave in certain ways when faced with a well-formulated set of alternatives and information. It is a normative theory; it suggests that people should act according to certain decision rules, but not that they will necessarily do so in reality. The standard assumption is that a person has a utility function over all possible outcomes, which defines the desirability or usefulness of any given scenario. Traditional utility theory asserts that in a decision without uncertainty, a person should choose the alternative resulting in the highest level of utility, and that in a decision with uncertainty, a person should choose the alternative with the highest expected utility. Detailed explanations are given by von Neumann and Morgenstern and Savage [1,2].

These ideas are generally sound and can be valuable when used as a guide for decision makers. However, it was initially thought that they were also valuable as a descriptive theory. It has since been determined that people violate normative decision theory in many clear and predictable ways. In this article, we introduce and discuss several of these interesting behavioral phenomena.

One of the earliest researchers to demonstrate a deviation from expected utility theory was Allais [3]. He distributed two surveys. In the first survey, respondents were asked to choose between the following

two options (original amounts were in francs):

Choice 1.

A:	\$1 million for sure
B:	0.10 probability of \$2 million 0.89 probability of \$1 million 0.01 probability of \$0

In the second survey, respondents were asked to choose between the following two options:

Choice 2.

C:	0.11 probability of \$1 million 0.89 probability of \$0
D:	0.10 probability of \$2 million 0.90 probability of \$0

The majority of respondents preferred *A* to *B*, and preferred *D* to *C*.

Choosing *A* and *D* appears to be reasonable. However, this example has been called the *Allais Paradox*, because these two choices contradict the idea that people are maximizing expected utility. If we let U_0 represent the person's utility for \$0, U_1 represent the person's utility for \$1 million, and U_2 represent the person's utility for \$2 million, then preferring *A* to *B* would imply that

$$U_1 > 0.10U_2 + 0.89U_1 + 0.01U_0,$$

or equivalently,

$$U_1 > \frac{10}{11}U_2 + \frac{1}{11}U_0.$$

If we examine the second survey choice, we find that preferring *D* to *C* implies that

$$0.11U_1 + 0.89U_0 < 0.10U_2 + 0.90U_0.$$

This may not seem like a problem at first glance. However, with simple

algebraic manipulation, we see that this is equivalent to

$$U_1 < \frac{10}{11}U_2 + \frac{1}{11}U_0.$$

This is the exact opposite result of what we saw in the first survey! It means that regardless of the utilities of the three outcomes, choosing both A and D (or both B and C) contradicts the theory of expected utility maximization.

Table 1 reveals the structure of the transformation of the first choice between A and B into the second choice between C and D . The final column corresponds to the 0.89 chance of the \$1 million outcome received in either A or B in the first choice. This \$1 million was replaced with a \$0 in both C and D in the second choice. Changing the amount of this “sure thing” of getting the same outcome of \$1 million in the 0.89 probability outcome in choice 1 to a different sure thing of \$0 in choice 2 should not change the preference order between the options. Savage (2, Postulate 2) called this the *sure-thing* principle, which must be obeyed under expected utility maximization.

This was one of the first clear demonstrations of a systematic violation of the principles of expected utility theory. That in itself is a very influential finding. However, we may want to ask why it happened. What element of people’s underlying preferences is not being captured by expected utility theory?

It turns out there are multiple explanations for Allais’ results, but the main reason they occurred is a phenomenon often referred to as the *certainty effect*. Reducing the probability of a negative outcome from 0.01 to 0 is usually judged to be a greater improvement than reducing the probability of that same negative outcome from, say, 0.90 to 0.89. Expected utility maximization requires

that preferences over gambles are linear in probabilities, and in Allais’ example, they clearly are not.

Another major finding in this area was discussed by Ellsberg [4]. He conducted an experiment in which subjects were presented with a jar. The subjects were told that the jar contains 30 red balls, and 60 balls which are some unknown mix of yellow and black. They were asked to choose between two gambles:

A:	Receive \$100 if the ball is red
B:	Receive \$100 if the ball is black

The majority of participants chose gamble A . They were then asked to choose between the following two gambles:

C:	Receive \$100 if the ball is red or yellow
D:	Receive \$100 if the ball is black or yellow

Given this choice, the majority of participants selected gamble D . As in the Allais’ example, choosing both A and D seems reasonable. However, this has been called the *Ellsberg Paradox*, because it is also a violation of expected utility theory. It may not be immediately clear how expected utility is violated, so let us write a participant’s estimated fraction of black balls as B , and observe the following contradiction:

Choosing A implies that

$$\begin{aligned} \frac{1}{3}U(\$100) + \frac{2}{3}U(\$0) &> BU(\$100) \\ &+ (1 - B)U(\$0). \end{aligned}$$

Assuming that $U(\$100) > U(\$0)$, this simplifies to $B < 1/3$.

Choosing D implies that

$$\begin{aligned} (1 - B)U(\$100) + BU(\$0) &< \frac{2}{3}U(\$100) \\ &+ \frac{1}{3}U(\$0). \end{aligned}$$

Table 1. Allais Paradox

	0.10	0.01	0.89
A	\$1 million	\$1 million	\$1 million
B	\$2 million	\$0	\$1 million
C	\$1 million	\$1 million	\$0
D	\$2 million	\$0	\$0

Assuming that $U(\$100) > U(\$0)$, this simplifies to $B > 1/3$.

Thus, there is no consistent set of beliefs (about the fraction of black balls and the fraction of yellow balls) which allows us, using traditional subjective expected utility theory, to prefer both gamble A and gamble D . That is, no single probability of drawing a black ball would lead to this pair of responses. However, there is a simple reason that most people choose both gamble A and gamble D : these are the choices for which we can easily compute the exact probability of receiving \$100. Ellsberg showed that not only do people display aversion to risk, they also display aversion to “ambiguity.” People tend to prefer gambles for which they are confident that they know the exact probabilities involved.

Table 2 shows the structure of this paradox. The choice between A and B is transformed by changing the sure thing of \$0 when a yellow ball is chosen to a sure thing of \$100 when yellow is chosen. So, if A is preferred over B , then C should be preferred over D .

Possibly the most groundbreaking work to bring violations of normative utility theory to a wide audience is from Kahneman and Tversky [5]. They highlighted two major behavioral violations of expected utility maximization, and demonstrated them using simple survey results.

Their first major violation resulted from a very simple pair of questions:

1. Would you prefer to receive \$3000 for sure, or \$4000 with probability 0.8?
2. Would you prefer to lose \$3000 for sure, or lose \$4000 with probability 0.8?

Expected utility maximization does not tell us precisely what the answers to these questions should be. However, notice that in

the second question, the expected value of losing \$4000 with probability 0.8 is $-\$3200$. It has greater risk than the sure loss, and a lower expected value. Preferring the gamble would imply that the person is risk-seeking. Utility curves formed over total wealth are almost always concave, implying risk aversion.

The answers to these two questions were startling. People (in aggregate) overwhelmingly preferred receiving \$3000 for sure in question 1, and overwhelmingly preferred losing \$4000 with probability 0.8 in question 2. That is, they were clearly risk-averse in question 1, and clearly risk-seeking in question 2. Kahneman and Tversky also asked similar types of questions in different contexts, using different probabilities and outcomes. In all cases, they found that the majority’s preferred answer to the question dealing with losses was the opposite of that for the question dealing with gains. They referred to this phenomenon as the *reflection effect*.

Since these people did not all have the same level of wealth, it would be impossible to construct a utility function over wealth that could incorporate the reflection effect and accurately represent these subjects’ responses. Instead, Kahneman and Tversky proposed that people evaluate outcomes as gains and losses rather than using the resulting total wealth levels. Based on their survey data, they postulated that people tend to be risk-averse over gains and risk-seeking over losses. Numerous subsequent studies have demonstrated this phenomenon, yet it is still not fully accepted or incorporated into traditional economic theory.

Kahneman and Tversky also found nonlinearities in probability, and expressed them in some more detail than Allais. In addition to certainty effects, they found that people tend to place too much weight on outcomes with very small (nonzero) probabilities. That is, they do not fully understand or incorporate how truly unlikely these outcomes are. They postulated that people treat probabilities according to the weighting function shown in Fig. 1. The horizontal axis represents the actual given probability, and the vertical axis represents the probability that people implicitly interpret it to be

Table 2. Ellsberg Paradox

	30 Balls Red balls	60 Balls are Either Black or Yellow	
		Black balls	Yellow balls
A \$100		\$0	\$0
B \$0		\$100	\$0
C \$100		\$0	\$100
D \$0		\$100	\$100

Figure 1. Nonlinear application of probabilities as observed by Kahneman and Tversky [5].

when making decisions. The “correct” interpretation of probability, as implied by traditional expected utility theory, is given by the 45 degree dotted line. This graph incorporates the certainty effect (at both zero and one), the overweighting of small probabilities, and the underweighting of middle and higher probabilities.

Another related behavioral phenomenon is what Tversky and Kahneman [6] referred to as *loss aversion*. Loss aversion states that a loss is deemed to be more significant than an equal-sized gain. The theoretical loss aversion concept explains two other more specific observed concepts. These two specific concepts are the *endowment effect* and the *status quo bias*.

The *endowment effect* is discussed by Thaler [7]. The premise is that the loss in utility from giving up an item is greater than the gain in utility from acquiring it. It was demonstrated experimentally by Kahneman *et al.* [8]. They asked subjects to place a monetary value on a cheap decorative mug. The catch was that some subjects had been given the mug beforehand, and others had not. Since the mugs were assigned randomly, there was no apparent reason that the underlying preferences should differ between those with mugs and those without. However, they found that the subjects who were given the mug placed *much* higher values on it than those who were not. In one experiment, the median value for the mug was \$7.12 among the subjects who had one, and \$3.12 among those who had not. In a second experiment,

these median values were \$7 and \$3.50, respectively. This was clear evidence that people tend to place much higher values on items they possess, or are “endowed” with.

The *status quo* bias was discussed by Samuelson and Zeckhauser [9]. *Status quo* bias is a preference for remaining in the current situation. The example that the authors used dealt with financial investments. They conducted an experiment in which several different funds were described to the participant. When participants were told that they currently had money invested in one of the funds, then they generally preferred that fund to the others. When they were given a “neutral” scenario in which they did not have money invested in any of the funds, then no such bias was observed.

Loss aversion explains both the endowment effect and the status quo bias. If a loss is more significant than an equal-sized gain (in terms of utility), then losing an item is clearly more significant than receiving that same item. It is not difficult to use loss aversion to explain the endowment effect. To understand the status quo bias, we can interpret a change as “losing” the current scenario and obtaining the new one. If the two scenarios are equally desirable when viewed from a neutral perspective, then loss aversion suggests that the decision maker will prefer the status quo.

Notice that in each of the two preceding examples, if the outcomes were viewed in terms of raw overall outcomes rather than gains and losses, the groups would be facing identical questions. In the endowment effect example, both groups would be expressing the difference in monetary value between a “mug” outcome and a “no mug” outcome. In the status quo bias example, each individual would be simply selecting the most desirable fund.

One implication of expected utility theory is that a person’s chosen course of action should not depend on the manner in which the alternatives are presented. If two decision situations involve the same outcomes with the same probabilities resulting from the corresponding alternatives, then the person’s decision should be identical for both. This property is called *invariance*. It is discussed by von Neumann and Morgenstern [1],

and studied further by Arrow [10]. Invariance is often violated in reality. These violations are referred to as *framing* effects.

Tversky and Kahneman [11] conducted a pair of surveys which demonstrated a clear framing effect. In both survey scenarios, a group of 600 people is about to be exposed to a deadly disease. In the first survey, the choice is whether to save 200 people for sure, or save all 600 with probability $1/3$ (and save nobody with probability $2/3$). The vast majority of participants chose the sure option. In the second survey, the choice is whether to allow 400 people to die for sure, or accept a $2/3$ probability of all 600 people dying (and a $1/3$ probability of nobody dying). The vast majority of participants chose the gamble.

Look at those two survey questions again. They are actually asking the same thing! One is framed in terms of number of lives saved, and the other is framed in terms of number of deaths. The outcomes and their associated probabilities, however, are identical. Simply due to the ways in which the situations are described, we find that many people's preferences are completely reversed. An observant reader may notice that this particular framing effect occurs because one question is described in terms of gains, and the other in terms of losses. Tversky and Kahneman [12] discussed this in greater detail. As prospect theory tells us, people tend to be risk-averse for gains and risk-seeking for losses.

One of the arguments in favor of using a risk-averse utility curve over wealth is the observation that most people will never accept a 50/50 gamble between gaining and losing $\$X$, regardless of the value of X . This implies a concave (risk-averse) utility function for wealth. Loss aversion is an alternative explanation for this observation; it asserts that " $-\$X$ " has a larger effect on utility than " $+\$X$ " does, without having to assess or incorporate wealth level.

Loss aversion, along with Kahneman and Tversky's earlier data, implies that rather than looking at potential overall wealth levels when making decisions, people tend to view outcomes as gains and losses relative to a particular reference level. Kahneman and Tversky's [5] prospect theory suggests that

Figure 2. The utility function associated with prospect theory Kahneman and Tversky [5].

people act according to a utility function¹ similar to the one shown in Fig. 2, where the slope of the utility is steeper when a loss of $\$X$ is incurred than when a gain of $\$X$ is incurred. This idea alone can explain many real-world deviations from traditional expected utility theory. Baucells and Rata [13] demonstrated empirically that using a reference point in this manner is an important factor in risk-taking behavior; Camerer [14] provides many additional real-world examples.

Given that people do not always conform to expected utility, there are different ways to proceed. One is to investigate how to aid people to do so. For example, Keller [15,16] investigated how different visual representations of gambles (most promisingly drawings of color coded balls labeled with the monetary amount that would be received if a ball is drawn) could lower violations of expected utility for questions similar to the Allais Paradox. Another approach is to relax the assumptions required by expected utility and

¹Kahneman and Tversky refer to this as a value function rather than a utility function, and it is generally understood to be an appropriate model for preferences under certainty. However, they proposed it initially based on observed preferences over gambles, as we have discussed earlier. Thus, to be consistent with our usage of the terms "value" and "utility," we refer to the curve in Fig. 2 as a utility function.

construct generalizations of expected utility, such as models that relax the requirement of linearity in probabilities. Kahneman and Tversky's [5] prospect theory is the most well-known generalized utility theory, but there are many others.

Becker and Sarin [17] introduced a lottery-dependent utility model that allows the utility achieved in an outcome to vary according to the lottery in which it occurs, but requires the true probabilities to be used. Their model was rather general, but can be used to explain some violations of expected utility. Daniels and Keller [18] tested this model experimentally, and found that it was useful in predicting choice among gambles, but not noticeably better than expected utility when actually determining decision makers' underlying preferences. Some other generalized utility models include weighted utility [19], regret theory (20, 21), and skew-symmetric bilinear utility [22,23]. For more examples and detailed discussion the reader is directed to Refs 24, 25, or 26.

In general, expected utility theory is quite valuable as a normative theory for guiding good decision making. However, between the certainty effect, ambiguity aversion, the reflection effect, the endowment effect, status quo bias, loss aversion, and framing effects, it is painfully apparent that people violate the traditional theory in many clear and predictable ways.

A final question for thought: in the real world, how often do these sorts of paradoxes and violations occur? Certainly the effects and biases that we have discussed do exist, but how often do they lead to incorrect or suboptimal decisions? If they occur very infrequently, then they are interesting as academic issues only. However, if they do come up reasonably often in the real world, then they undoubtedly merit further study and awareness.

PARALLEL SYSTEM VERSUS SERIES SYSTEM

In the area of reliability, the primary goal is to ensure that a system will function adequately with a high probability. For instance, Clements [1] noted that due to safety reasons, command systems in aircrafts require high probability of functioning. Moreover, it may be desired to maintain a minimum acceptable level in which a system will function. The papers by Kvam and Peña [2] and Sinkovic, Lovrek, and Nemeth [3] modeled how a load can be shared by components in a system in such a way that failure of a component will require the remaining components to compensate for the failed component.

In certain cases, components are connected in a manner where system failure will only be observed as soon as all components have failed. Such a system is known as a *parallel system*. In contrast to a series system (see **Series Systems** in this encyclopedia) where a system fails as soon as a component has failed, a parallel system continues to function as long as at least one component is still functioning. A partial listing of papers that compare a series system and a parallel system include Refs 4 and 5. On the other hand, the papers [6–8], among others, considered the similarity between a parallel system and a system of redundant components. Finally Refs 9 and 10 are some of the recent papers that investigated the failure in the interaction of components in a parallel system.

The probability of observing a functioning system is known as the *system reliability*. The system reliability depends on the manner in which components are connected and the

individual component reliability is usually observed as a function of time. In this paper, we will formulate the system reliability for a parallel system and consider an example in which the individual component reliability will depend on some known probability distribution.

SYSTEM RELIABILITY

Structure Function of a Parallel System

We consider a system of n components such that the state of the system, that is, whether the system is functioning or has already failed, depends on how the components are connected and the current state of each component. Let binary variable X_i indicate whether component i is still functioning, denoted by $X_i = 1$, or has failed, denoted by $X_i = 0$. Each component is assumed to be independent the other resulting in independent random variables $X_1, \dots, X_n$. The vector $\mathbf{X} = (X_1, \dots, X_n)$ is the state vector for a system of n components. On the other hand, the binary function $\phi(\mathbf{X})$ represents the state of a system, that is, $\phi(\mathbf{X}) = 1$ if the system is still functioning and $\phi(\mathbf{X}) = 0$ if the system has failed. For a more detailed discussion of the properties of X_i and $\phi(\mathbf{X})$, the reader is referred to articles **Coherent Systems** and **Series Systems** in this encyclopedia.

A parallel system is a system that functions if and only if at least one component is functioning. From a different point of view, a parallel system fails as soon as all components have failed. Owing to the binary nature of X_i , it follows that $1 - X_i = 1$ whenever component i has failed. Clearly, the events $\{\phi(\mathbf{X}) = 0\}$ and $\{X_1 = 0, \dots, X_n = 0\}$ are equivalent, and $\{\phi(\mathbf{X}) = 1\} = \{\text{at least one } X_i = 1\}$, and thus the structure function of a parallel system is

$$\begin{aligned}\phi(\mathbf{X}) &= 1 - (1 - X_1) \cdots (1 - X_n) \\ &= 1 - \prod_{i=1}^n (1 - X_i).\end{aligned}\tag{1}$$

2 PARALLEL CONFIGURATIONS

An alternative way of expressing the structure function of a parallel system is

$$\phi(\mathbf{X}) = \max(X_1, \dots, X_n).$$

Figure 1 presents a diagram for a parallel system with two components.

Reliability of a Parallel System

Consider a parallel system that is observed at a specified time instant t . To indicate this time-dependence in our notation, let $X_i(t)$ indicate the state of component i at t . The corresponding state vector is $\mathbf{X}(t) = (X_1(t), \dots, X_n(t))$. Let $p_i(t)$ be the probability that component i is functioning at time t . In terms of $X_i(t)$, we have

$$p_i(t) = \mathbf{P}\{X_i(t) = 1\}, \quad i = 1, \dots, n.$$

If we let $\mathbf{p}(t) = (p_1(t), \dots, p_n(t))$, then the system reliability at time t is defined to be

$$h(\mathbf{p}(t)) = \mathbf{P}\{\phi(\mathbf{X}(t)) = 1\} = \mathbf{E}[\phi(\mathbf{X}(t))].$$

For a parallel system, it is more convenient to write the system reliability in the form

$$h(\mathbf{p}(t)) = 1 - \mathbf{P}\{\phi(\mathbf{X}(t)) = 0\}.$$

By the independence of the $X_i(t)$'s, we get

$$\begin{aligned} h(\mathbf{p}(t)) &= 1 - \mathbf{P}\{X_1(t) = 0, \dots, X_n(t) = 0\} \\ &= 1 - \mathbf{P}\{X_1(t) = 0\} \cdots \mathbf{P}\{X_n(t) = 0\}. \end{aligned}$$

Figure 1. Diagram for a parallel system with two components.

Thus, the reliability of a parallel system at time t is

$$\begin{aligned} h(\mathbf{p}(t)) &= 1 - [1 - \mathbf{P}\{X_1(t) = 1\}] \cdots \\ &\quad \times [1 - \mathbf{P}\{X_n(t) = 1\}] \\ &= 1 - \prod_{i=1}^n [1 - p_i(t)]. \end{aligned}$$

TIME-DEPENDENT SYSTEM RELIABILITY

Survival Function for a Parallel System

We now consider a parallel system where each component's failure process is a function of the time the component has been in use. In other words, we consider a random variable T_i denoting the lifetime of component i with corresponding probability density function $f_i(t; \theta)$ for some parameter vector θ . Following Ref. 11, we define the survival function (or reliability function) and the hazard function of component i at time t to be

$$\begin{aligned} S_i(t; \theta) &= \mathbf{P}\{T_i > t\} \\ &= \int_t^\infty f_i(u; \theta) du \quad \text{and} \\ h_i(t; \theta) &= \frac{f_i(t; \theta)}{S_i(t; \theta)}, \end{aligned}$$

respectively. We will assume that $T_1, \dots, T_n$ are independent random variables. Since all the n components have random lifetimes, the system lifetime, denoted by Y , is also a random variable. Extending Equation (1), it is easily seen that

$$Y = \max(T_1, \dots, T_n). \quad (2)$$

Whenever a system is in use, the main interest is to obtain the survival function and the hazard function of Y . Note that the survival function of Y is the system reliability as we have previously defined. From Equation (2),

$$\begin{aligned} S(y; \theta) &= \mathbf{P}\{\max(T_1, \dots, T_n) > y\} \\ &= 1 - \mathbf{P}\{\max(T_1, \dots, T_n) \leq y\} \\ &= 1 - \mathbf{P}\{T_1 \leq y, \dots, T_n \leq y\}. \end{aligned}$$

By the independence of the component lifetimes, the resulting system reliability is

$$\begin{aligned} S(y; \theta) &= 1 - \prod_{i=1}^n P\{T_i \leq y\} \\ &= 1 - \prod_{i=1}^n [1 - S_i(y; \theta)], \end{aligned} \quad (3)$$

where $S_i(t; \theta)$ is the survival function of the i th component. The corresponding density function of the system lifetime for a parallel system is

$$\begin{aligned} f(y; \theta) &= - \sum_{i=1}^n S'_i(y; \theta) \prod_{\substack{j=1 \\ j \neq i}}^n [1 - S_j(y; \theta)] \\ &= \sum_{i=1}^n f_i(y; \theta) \prod_{\substack{j=1 \\ j \neq i}}^n [1 - S_j(y; \theta)]. \end{aligned} \quad (4)$$

The hazard function of Y is easily obtained by taking the quotient of the density function and reliability function obtained from Equations (4) and (3), respectively. In a more specific case when the component lifetimes are identically distributed with density function $f_*(t; \theta)$ and survival function $S_*(t; \theta)$, the system reliability function and density function of the system lifetime Y become $S(y; \theta) = 1 - [1 - S_*(y; \theta)]^n$ and $f(y; \theta) = n f_*(y; \theta) [1 - S_*(y; \theta)]^{n-1}$, respectively.

Exponential Lifetimes

We will now consider a parallel system consisting of components whose lifetimes are exponentially distributed. The component lifetimes are assumed to be independent of one another but not necessarily identically distributed. Hence, the density function of the i th component lifetime, T_i , is

$$f_i(t; \theta_i) = \theta_i e^{-\theta_i t}, \quad \theta_i > 0.$$

Some recent papers that considered exponential lifetimes for a parallel system include Refs 4 and 12–14. For a more detailed discussion of the exponential distribution, the reader is referred to articles **Common Failure Distributions** and **Series Systems** in this encyclopedia.

We let $Y = \max(T_1, \dots, T_n)$ denote the lifetime of the parallel system and the vector $\theta = (\theta_1, \dots, \theta_n)$ the scale parameter vector. From Equation (3), the system reliability of a parallel system is

$$S(y; \theta) = 1 - \prod_{i=1}^n (1 - e^{-\theta_i y}).$$

Since $S'_i(y; \theta) = -f_i(y; \theta)$, it follows from Equation (4) that the density function of Y is

$$f(y; \theta) = \sum_{i=1}^n \theta_i e^{-\theta_i y} \prod_{\substack{j=1 \\ j \neq i}}^n (1 - e^{-\theta_j y}).$$

Whenever the component lifetimes are also identically distributed, that is, $\theta_i = \theta$ for $i = 1, \dots, n$, the system reliability and density function become

$$\begin{aligned} S(y; \theta) &= 1 - (1 - e^{-\theta y})^n \quad \text{and} \\ f(y; \theta) &= n \theta e^{-\theta y} (1 - e^{-\theta y})^{n-1}, \end{aligned}$$

respectively. Consequently, in this special case the hazard function of a parallel system is

$$h(y; \theta) = \frac{f(y; \theta)}{S(y; \theta)} = \frac{n \theta e^{-\theta y} (1 - e^{-\theta y})^{n-1}}{1 - (1 - e^{-\theta y})^n}.$$

Let us examine the behavior of the hazard function $h(y; \theta)$ as $y \rightarrow \infty$. It has been shown in the literature that $\lim_{y \rightarrow \infty} h(y; \theta) = \min(\theta_1, \dots, \theta_n)$ and in particular, $\lim_{y \rightarrow \infty} h(y; \theta) = \theta$ in the identically distributed case. Thus, the limit of the hazard function of a parallel system is the same as the hazard function of the strongest exponential component of the system.

University, Miami, Florida

SIMULATION AND PARALLELIZATION METHODS

Discrete-Event Simulation

Simulation, defined as a representation of the operation of real-world processes or systems over time [1], is one of the most important and widely used techniques in operations research. These processes or systems are abstracted as models in the form of mathematical or logical relationships. In simulation, one uses computers to evaluate the models numerically in a controlled environment, where data are gathered and used to estimate the behavior of the target systems. Simulation is effective for prototyping new system designs, as well as providing insight to the true characteristics of existing systems. Simulation is particularly indispensable for studying large-scale and complex systems, which can be otherwise intractable to closed-form mathematical or analytical solutions. Owing to the practical nature of the design process where simplified assumptions fly in the face of required complexities, simulation is an irrefutable choice for both system design and evaluation.

A simulation model specifies the state evolution over time. The target system can be viewed either as a *continuous* system, where the state changes continuously with respect to time; as a *discrete* system, where the state is modified only at specific points in time; or as a *hybrid* system, which consists of both continuous and discrete elements. In simulation, time progression is described by the so-called “time advancement function,” the treatment of which signifies two classes of

simulation methods: time-driven and event-driven. In a *time-driven* (or *time-stepping*) simulation, time is measured at small intervals giving the impression that the system evolves continuously over time. As such, it is naturally more suitable for simulating continuous systems.

In an *event-driven* (or *discrete-event*) simulation, time leaps through distinct points in time, which we call *events*. Consequently, event-driven simulation is more appropriate for simulating discrete systems. Note that one can combine both types of simulations, for example in a computer network simulation, using discrete events to represent detailed network transactions such as sending and receiving packets, and using continuous simulation to capture the fluid dynamics of overall network traffic [2].

This article mainly focuses on discrete-event simulations and efficient techniques to parallelize them. It is necessary to first understand what constitutes a discrete-event simulation before we proceed to review the parallelization methods. At the application level, modelers can describe the processing of events using three major kinds of simulation worldviews (also known as *simulation paradigms*): event-oriented, process-oriented, and activity scanning. The *event-oriented* worldview focuses on events and their effects on the state of the simulation. Event handlers are defined and used in the simulation program to process events of different types. Event-oriented worldview provides the lowest modeling perspective and yet, the most efficient mechanism among the three worldviews.

The *process-oriented* worldview describes a higher level of modeling abstraction than does the event-oriented worldview. A model is expressed as a set of interacting simulation processes, each being a thread of control that describes the state evolution over time. A simulation process usually has a life cycle longer than just a single event, and is provided with mechanisms to interact with other simulation processes: a process can wait for

a period of simulation time to elapse or some specific events to happen, such as the arrival of a message. It is important to note that the process-oriented worldview can be implemented on top of an event-oriented simulation engine with additional support for thread management.

The third kind of simulation worldview is called *activity scanning*. It is closely related to time-driven simulation. A collection of procedures are provided, each associated with a predicate. At each timestep, all predicates are evaluated and the corresponding procedures are invoked if the predicates turn out to be true. All simulation worldviews are merely user perspectives, which can be supported by the same discrete-event simulation engines. We choose to focus on the event-oriented worldview in this article as it is closest among the three simulation worldviews to the underlying discrete-event simulation mechanism, which we seek to parallelize.

A discrete-event simulator maintains a data structure called the *event list*, basically a priority queue that sorts events according to the time at which they are scheduled to happen in the simulated future. A clock variable T is used to denote the current time in simulation. At the heart of the program is a loop; the simulator repeatedly removes an event with the smallest time stamp from the event list, sets the clock variable T to the time stamp of this event, and processes the event. Processing an event typically changes the state of the model and may generate more future events to be inserted into the event list. The loop continues until the simulation termination condition is met; for example, when the event list becomes empty or when the simulation clock has reached a designated simulation completion time.

Parallelization Methods

Parallel discrete-event simulation (PDES), also known simply as *parallel simulation*, is an important research area cross-cutting modeling and simulation, and high-performance computing. PDES is concerned with executing a single discrete-event simulation program on parallel computers, which can be shared-memory multiprocessors, distributed-memory clusters of

interconnected computers, or a combination of both. By exploiting the potential parallelism in the model, PDES can overcome the limitations imposed by sequential simulation in both the execution time and the memory space. As such, PDES can bring substantial benefits to time-critical simulations and simulations of large-scale systems that demand a tremendous amount of computing resources.

The simplest form of parallel simulation is called *replicated trials* [3]. This method executes multiple instances of a sequential simulation program concurrently on parallel computers. These “replicated” trials may be replications belonging to the same experiment (e.g., started off with different random seeds), or separate simulation runs with different model parameters. This approach has the obvious advantage of simplicity. It can be an efficient variance reduction method or a method for expediting the exploration of a large parameter space. The disadvantage is that each replicated trial does not provide any speedup and cannot overcome the memory limitation imposed upon sequential execution. To address the latter problem, Hybinette and Fujimoto [4] introduced a cloning method as an efficient parallel computation technique to allow simultaneous exploration of different simulation branches resulted from alternative decisions made during simulation.

Another form of parallel simulation is to assign different functions of a simulation program, such as random number generation or event handling, to separate processors. This method is called *functional decomposition* [5]. The main problem of this approach is the lack of ample parallelism. Also, the tight coupling of the simulation functions creates an excessive demand for communication and synchronization among the parallel components, which can easily defeat the parallelization effort.

More generally, one can view simulation as a set of state variables that evolve over time. Chandy and Sherman [6] presented a space-time view of simulation, where each event can be characterized by a temporal coordinate, indicated by the time stamp of the event, and a spatial coordinate, indicated

by the location of the state variables affected by the event. Accordingly, the state space of a discrete-event simulation can be perceived as consisting of a continuous time axis and a discrete space axis; the objective of the simulation in general is therefore to compute the value at each point in the space–time continuum. This space–time view provides a high-level unifying concept for parallel simulation, where one can divide the space–time graph into regions of arbitrary shape and assign them to separate processors for parallel processing. For example, Bagrodia *et al.* [7] presented a distributed space-time algorithm based on fixed-point computations.

A special case of the space–time view is the *time-parallel* approach, which is based on temporal decomposition of the time–space continuum. Time-parallel simulation divides the space–time graph along the time axis into nonoverlapping time intervals and assigns them to different processors for parallel processing. Due to the obvious dependency issue, that is, the initial state of a time interval must match the final state of the preceding time interval, the efficiency of this approach relies heavily on the model’s ability to either rapidly compute the initial state or achieve fast convergence under relaxation. For this reason, only a limited number of cases using time-parallel simulation exist in the literature. Successful examples include trace-driven cache simulations [8,9], queueing network and Petri net simulations [10,11], and road traffic simulations [12].

Orthogonal to the time-parallel approach, *space-parallel* simulation is based on data decomposition, where the target system is divided into a collection of subsystems, each simulated by a *logical process (LP)*. Each LP maintains its own simulation clock and event list, and is capable of processing only those events that pertain to the subsystem to which it is assigned. These LPs can be assigned to different processors and executed concurrently. Communication between the LPs takes place exclusively by exchanging time-stamped events. In general, space-parallel simulation is considered more robust than the other parallelization approaches, mainly because data decomposition can be naturally

applicable to most models. For this reason, we focus on space-parallel simulation for the rest of this article.

SYNCHRONIZATION ALGORITHMS

In a discrete-event simulation, events need be processed in a nondecreasing time stamp order, because an event with a smaller time stamp has the potential to modify the state of the system and thereby affect events that happen later. This property is called the *causality constraint*. Provided that simultaneous events—events with the same time stamps—are sorted deterministically and consistently using certain tie-breaking rules, the causality constraint implies a total ordering of events. In parallel simulation, the global event list in sequential simulation is replaced by a set of event lists; each LP maintains its own simulation clock and a separate event list that contains events that can only affect the state of the corresponding LP. Since each LP processes events on its own event list in time stamp ordering—a property also known as the *local causality constraint*—the total ordering maintained by the original sequential discrete-event model is replaced by a partial ordering similar to Lamport’s “happens before” relationship [13]. The fundamental challenge is therefore associated with the difficulty of preserving the local causality constraint at each LP without the use of a global simulation clock as LPs advance their own simulation clocks more or less independently from one another.

We use a simple example to illustrate this problem (Fig. 1). Suppose there are two interconnected queues, A and B, with jobs in both queues waiting to be serviced. After a job is serviced at one queue, it joins the other queue after a certain delay. There are two types of simulation events: one representing the job arrival and the other representing the job departure. The two queues are simulated by two LPs running on two separate processors. Upon processing the “job departure” event at one LP, a “job arrival” event will be sent from the LP to the other LP. Figure 1 shows that a job enters Queue A at time 4 (represented by $E1$), departs at 10 ($E3$), and then

Figure 1. Simulation of two queues.

travels to Queue B at 14 ($E4$), while another job enters Queue B at time 7 ($E2$) and leaves at 19 ($E5$). Since the two queues are simulated on separate processors, it is possible that the LP handling Queue B gets to process $E5$ immediately after processing $E2$, while the other LP is still in the middle of processing $E1$ at Queue A. That is, it is probable that an event (in this case, $E4$) could arrive from the other LP later in real time carrying a time stamp smaller than the LP's current simulation clock.

To avoid potential causality errors, some synchronization mechanism needs to be in place. Specifically, an LP must be able to make the right decision about whether to process the smallest time-stamped event on its local event list.

The distinction on how local causality constraint is enforced underscores the difference between two major parallel simulation methods. *Conservative parallel simulation* eliminates the possibility of any causality errors; that is, an LP must be blocked from processing the next event in its event list until it is sure that processing such event will not cause out-of-order event execution due to future events to arrive from other LPs.

In contrast, *optimistic parallel simulation* allows events to be processed out of order. Once a causality error is detected, the offending LP must be rolled back to recover from such an error. In order for the simulation to roll back from possible erroneous computations, state saving and recovery mechanisms must be provided.

CONSERVATIVE SYNCHRONIZATION

The conservative approach strictly prohibits out-of-order event execution: an LP must be

blocked from processing the next event in its event queue until it is safe to do so. Synchronization needs to take place among the LPs to ensure that no event will arrive at an LP with a time stamp earlier than its local simulation clock.

CMB Algorithm

The first parallel simulation synchronization protocol is the *CMB algorithm* proposed independently by Chandy and Misra [14], and Bryant [15].

In CMB, LPs are connected via directional links, through which events are transferred from one LP to another in chronological order (with nondecreasing time stamps). Events are enqueued at the receiving LPs, there is one input queue for each incoming link at an LP. Also, each input queue is associated with a clock variable, set to be either the time stamp of the first event in the queue, or, if the queue is empty, the time stamp of the last processed event (or zero initially). Each LP maintains a loop: at each iteration, the LP selects an input queue with the smallest clock value and processes the event at the beginning of the input queue; if the input queue is empty, the LP blocks until an event arrives at the queue and then continues at the next iteration.

Since LPs block on empty input queues (with the smallest clock value), deadlock may happen once a waiting cycle is formed, in which case no progress can be made even if there are events in other input queues. The CMB algorithm uses *null messages* to avoid this pathological situation. A null message does not represent any real activities in the model; it carries only a time stamp, which can be treated as a guarantee from the sending LP that it will not send events in the

future with time stamps smaller than the time stamp of the null message. Upon receiving a null message, an LP can advance the clock associated with the input queue. The LP can further propagate the time advancement to its successor LPs, possibly by sending out more null messages. Consequently, no waiting cycle can be formed and deadlock is avoided.

It is important to note that the use of null messages is not the only way to prevent deadlocks. Alternatively, one can allow deadlock to happen, and subsequently detect and recover from deadlock situations [16]. Deadlock recovery is based on the observation that events with the smallest time stamp in the system can always be processed safely. In cases where deadlocks happen more frequently, however, this may result in a significant amount of sequential execution that can adversely affect the overall performance.

Exploiting Lookahead

The CMB algorithm introduced an important concept regarding event processing. Each LP must determine the lower bound on the time stamps (LBTS) of future events to arrive from other LPs. LBTS is actually the upper bound up to which the LP can safely process its local events and advance its simulation clock without introducing causality errors. CMB uses a small time increment above the LP's current simulation clock as the time stamp of the null messages it sends to the successor LPs. This is the essential idea behind the concept of *lookahead*, which is defined as the amount of simulation time that an LP can predict into the simulated future (and therefore allow other LPs to safely advance their simulation clocks). In other words, lookahead is the inherent asynchrony in the simulation model—with a positive lookahead, an LP can process events within a certain range independent of its neighbors. Extensive performance studies [17–19] confirmed the positive correlation between lookahead and the parallel performance of conservative algorithms.

Exploiting lookahead takes on two directions. One direction focuses on extracting lookahead from model characteristics. Nicol [20] provided a classification of lookahead

based on different levels of knowledge that can be extracted from the model. Several models exhibit good lookahead properties. A notable example is the simulation of first-come-first-served (FCFS) stochastic queueing networks [21]. By presampling the job service time and determining branch destination at the time when a job enters the queue, one can significantly improve the lookahead. Another example is the simulation of continuous-time Markov chains (CTMC) [22–24]. The method exploits the mathematical structure of CTMC models (more specifically, the uniformization property) that allows the preselection of synchronization points ahead of time. Consequently, the synchronization complexity can be reduced significantly due to the improved lookahead.

The other direction focuses on lookahead extrapolation for general applications. Chandy and Sherman's *conditional-event* approach [25] takes into account two types of events: *definite* events, which are bound to happen regardless of the earlier events, and *conditional* events, which can be canceled because of earlier events. This algorithm requires each LP to determine the LBTS of future events it will send to each of its neighbor LPs on the premise that its earliest local conditional event will not be canceled. This lower bound can be calculated as the time stamp of the earliest conditional event on the local event list plus the lookahead. Since the earliest conditional event in the system is actually a definite event, the algorithm uses a global min-reduction to find out the true lower bound and use it as the LBTS for all LPs to process their local events.

The topology of the model—how LPs are connected with each other—plays an important role in the lookahead computation. Lubachevsky's *bounded lag* algorithm [26] takes advantage of the minimum propagation delay between LPs and the so-called opaque period within which the state of an LP is not affected by other LPs due to the model's non-preemptive behavior. The algorithm introduces a time interval B , called the *lag*, through which the algorithm computes the “sphere of influence”, which

is the set of LPs that can possibly affect a given LP within B units of simulation time. These are the LPs that need to be considered to determine whether events on the given LP with time stamps between T (the current simulation time) and $T + B$ can be safely processed. Ayani's *distance-between-objects* algorithm [27] also exploits the distance between the LPs; it uses a shortest-path algorithm to determine the LP's LBTS. The *time-of-next-event* algorithm proposed by Groselj and Tropper [28] also explores LP topology; the algorithm considers situations where multiple LPs reside on a single processor and allows efficient computation of the greatest lower bound of all LPs on a processor. Nicol [29] established a scalability analysis based on a window-based synchronization algorithm. The algorithm is similar to the conditional-event approach in that it also uses a global min-reduction to determine the time of the next synchronization point.

In a certain way, LP-based conservative synchronization methods can be viewed as a scheduling problem where LPs are selected to run on parallel processors. Xiao *et al.* [30] introduced an asynchronous multilevel LP-scheduling algorithm, called the *critical channel traversing* (CCT) algorithm, to accommodate simulation models with small computational granularity. CCT schedules groups of LPs among the processors using a shared data structure to reduce unnecessary low-level synchronization overheads. Nicol and Liu [31] proposed a composite synchronization scheme combining both synchronous and asynchronous scheduling algorithms to avoid the potential performance pitfalls from either synchronous or asynchronous mechanisms used alone.

OPTIMISTIC SYNCHRONIZATION

Optimistic synchronization enforces the local causality constraint differently from its conservative counterpart: an LP is allowed to process events that arrive in the simulated past, as long as the simulation is able to detect such causality errors, rewind the simulation clock, and roll back the erroneous computations.

Time Warp

It is safe to say by and large that Jefferson's *Time Warp* algorithm [32] is the most far-reaching parallel synchronization protocol. The protocol was first conceived to be offering a general solution to all parallel simulation problems, although the overhead associated with many aspects of the protocol's execution eventually caught up. In retrospect, the protocol set forth an era of intensive research in the PDES field.

In Time Warp, each LP saves the events received from other LPs in the input queue, and those sent to other LPs in the output queue. Also, the state variables are saved in the state queue each time before an event is processed. When an event arrives with a time stamp smaller than the current simulation clock (called the *straggler* event), the LP must be rolled back to the saved state immediately before the time stamp of the straggler event. All actions that the LP might have affected on other LPs later than the time stamp of the straggler event must also be canceled. This can be achieved by sending *anti-messages* corresponding to the original messages that are stored at the output queue. Upon receiving an anti-message, the LP will annihilate the corresponding message in the input queue. If the anti-message carries a time stamp smaller than the LP's current simulation clock (and thus become a straggler event itself), the LP will also be rolled back accordingly.

Simple and elegant as it appears to be, the algorithm must address the important issue of memory consumption: as the simulation progresses, the size of the input, output, and state queues could increase without bound. Furthermore, since rollback does not apply to irrevocable operations, such as I/O, the algorithm must also determine when these irrevocable operations can be executed. The *global virtual time* (GVT) is defined as the minimum time stamp of all events and messages (including both positive messages and anti-messages) in the system at a given wall-clock time. One can show that the system will never roll back to a time earlier than GVT. As such, GVT can be viewed as a measure of progress, where messages or state vectors

earlier than GVT can be reclaimed (in a process called *fossil collection*). Similarly, irrevocable operations that happen before GVT can also be committed. Another important problem with Time Warp is containment. As indicated in a paper by Nicol and Liu [33], a correct simulation program that runs sequentially may fail catastrophically due to an unpredictable inconsistent state resulted from out-of-order event execution. Such failures must be captured or contained by the Time Warp simulation engine (not without significant undertaking to modify operating system services), so that a failed state can be rolled back when Time Warp corrects itself.

Time Warp also needs to overcome several practical problems pertaining to its performance: state saving inevitably introduces memory overhead; rollback entails more complexities, where state needs to be restored, and anti-messages need to be sent, which can possibly cause further rollbacks rippling through the entire system. These problems have prompted a lot of interesting research, some of which we describe next.

State Saving, GVT, and Rollback

State saving is necessary to undo modifications to the state variables, caused by erroneous computations. There are three types of state-saving techniques: *copy state saving* makes a copy of all state variables each time an event is processed; *incremental state saving* saves only those state variables modified as a result of processing an event; and *infrequent state saving* adjusts the interval between checkpoints and reduces the frequency of state saving. Incremental state saving can be made automatic, by overloading the assignment operators in certain object-oriented programming languages [34], by using specific hardware support [35], or by directly modifying the executable files [36]. To enable infrequent state saving, the rollback mechanism must be able to handle situations where an LP may be rolled back to a state not immediately before the straggler event. In this case, the LP must *coast forward*, reprocessing events until the desired state is reached. For this reason infrequent state saving must be applied judiciously. Lin *et al.* [37] studied the trade-off between

the state-saving interval length and the rollback cost, and suggested an analytically optimal solution.

GVT computation is a major source of overhead for Time Warp. The task of computing GVT amounts to capturing a consistent snapshot of the state of a distributed system. According to Samadi [38], there are two major issues: the *transient message* problem and the *simultaneous reporting* problem. A transient message is a message that has been sent but not yet received; either the sender or the receiver LP must account for the message in the GVT computation, or inconsistencies would occur. Simultaneous reporting is also related to the possible miscount of transient messages; it is, however, prompted by the difference in the ordering of events perceived by different LPs. Samadi's algorithm [38] employs a message acknowledgment scheme to solve the transient message problem and adopts a barrier synchronization method to solve the simultaneous reporting problem. To avoid the expensive barrier synchronization, Preiss's algorithm [39] arranges the LPs in a ring and uses a token traversal approach to compute GVT. Mattern's algorithm [40] uses two broadcasts to define separate "cuts" and uses messages with "colors" to distinguish those spanning across the cuts.

Optimizations can also be applied to reduce the overhead from rollbacks. Gafni [41] proposed *lazy cancellation* to avoid canceling messages that are more likely to be recreated after rollbacks. The algorithm does not immediately send anti-messages during a rollback; instead, they are sent only when the same positive messages are not recreated. West [42] proposed another method called *lazy reevaluation* to avoid reprocessing the events, which can be achieved by comparing the state vectors. Both methods require additional time for comparing messages or state vectors, which could cause erroneous computation to be spread further.

One interesting alternative to the state-saving approach is *reverse computation*, proposed by Carothers *et al.* [43]. Rather than saving the state to enable rollback, reverse computation performs the inverses of the individual operations that correspond

to the normal event processing (i.e., by executing the code backwards) to get the system back to an earlier state. This method alleviates the state-saving cost from the forwarding computation path and transfers the cost to the reverse computation path. It can also be viewed as trading the memory space (which would otherwise be consumed by state saving) with the execution time (for the more expensive rollback). Significant improvements over traditional state-saving methods have been reported both in run time and memory utilization for fine-grain models, including queueing network models. One potential problem for reverse computation is that not all operations are reversible, in which case the method is degenerated to the traditional state-saving approach. The increased rollback cost may also get erroneous computations to be propagated to more LPs, possibly causing unstable behavior.

Curbing Optimism

In practice, “pure” Time Warp usually does not provide an acceptable performance. Many alternative solutions have been proposed that effectively limit optimistic execution to circumvent various performance hazards.

Lin and Preiss [44] first introduced the concept of *storage optimality*. A storage optimal parallel simulator can complete the execution of any model using no more than the memory space required to complete a sequential execution multiplied by some constant factor. To achieve storage optimality, a necessary condition is that the parallel simulator should be able to reclaim the memory space beyond the sequential execution requirement, even if it implies restraint in the speculative execution. Several algorithms run on shared-memory multiprocessors qualify for the storage optimality, which includes Jefferson’s *cancel-back* algorithm [45], and Lin and Preiss’s *artificial rollback* algorithm [44]. Preiss and Loucks’s *prune-back* algorithm [46] is designed for distributed-memory architectures; however, it fails to meet the storage optimality requirement.

A number of optimistic parallel simulation algorithms are proposed to curb optimism.

For example, the *moving time window* approach [47] uses a window to control how far an LP may get ahead of other LPs. The effectiveness of this algorithm obviously depends on the size of the moving time window.

Reynolds [48] introduced a classification method for optimistic synchronization protocols based on two attributes: *aggressiveness* and *risk*. Aggressiveness specifies that events on an LP can be processed out of time stamp order, where risk suggests that messages generated by aggressive event processing are allowed to be sent to other LPs. For example, the SRADS protocol by Dickens and Reynolds [49] is aggressive, but allows no risk: it permits only local rollbacks; messages are not sent unless the LP is sure that the messages will not be rolled back. As an extension, the *breathing time bucket* approach, proposed by Steinman [50], introduced a quantity called an *event horizon*. An LP’s local event horizon is the smallest time stamp of any new messages that are generated as a result of processing local events. The global event horizon can be computed as the minimum of the local event horizons among all LPs. The algorithm allows only messages with a sending time prior to the global event horizon to be sent out. By doing that, it can be shown that these messages will never be rolled back.

Many have tried to compare conservative and optimistic simulations; yet it comes as no surprise that there is no conclusive answer to which is a better approach. This is mainly because parallel simulation performance largely depends on the characteristics of the simulation model. On the one hand, conservative synchronization, due to its low operational overhead and small memory footprint, can usually achieve good performance as long as good lookahead can be guaranteed from the model. On the other hand, the optimistic approach can exploit better parallelism in the model through speculative execution. However, optimistic execution requires state saving, GVT computation, fossil collection, and rollbacks, which could bring in significant design complexity and memory overhead.

HIGH-PERFORMANCE MODELING AND SIMULATION OF LARGE-SCALE NETWORKS

PDES has been applied in many areas, such as military applications (including war games and training exercises), on-line gaming, business operations, manufacturing, logistics and distribution, transportation, computer systems, and computer networks. In this section, we review the latest development in high-performance modeling and simulation of large-scale computer networks as an example of successful PDES applications.

Internet is described by Paxson and Floyd [51] as “an immense moving target”: its size, heterogeneity, and rapid change pose a daunting challenge for accurately simulating its complex behavior. Over the last ten years or so, researchers have developed several parallel simulators that can model networks at unprecedented scales. For example, Riley *et al.* [52] used a federated approach to parallelize the popular *ns-2* simulator [53]. The original sequential discrete-event simulation engine is “refurbished” with parallel functions to allow time-synchronized event distribution. There are also unadulterated efforts in developing parallel network simulations from scratch. One early effort is the Telecommunications Description Language (TeD) proposed by Perumalla *et al.* [54], which allows parallel execution of large network models with an optimistically synchronized parallel simulation engine.

The Scalable Simulation Framework (SSF) was later developed as a common Application Programming Interface (API) for parallel simulations of large-scale telecommunication systems [55]. SSF is different from TeD in that it does not require a separate programming language; SSF network models are written in common programming languages (Java or C++) using simple simulation constructs that support transparent conservative parallel execution on different platforms. A similar effort is the Georgia Tech Network Simulator (GTNetS) [56], which is a full-fledged simulation environment embellished with a rich set of network protocol implementations. The GTNetS effort has recently evolved into *ns-3* [57], which is a renewed effort for

open community development of network simulations. Both SSF and GTNetS are developed based on conservative synchronization protocols. ROSSNet [58], on the other hand, is a large-scale network simulator using an optimistic approach. It offers a compact and light-weight implementation framework that reduces the amount of state required to simulate large-scale network models. ROSSNet uses reverse computation to enable fast optimistic execution on commodity multiprocessor systems.

Two important application areas using high-performance network simulation have shown very promising results: on-line simulation and real-time simulation. *On-line network simulation* refers to the use of network simulation as an integrated service for real-time network management for parameter tuning, network planning, network monitoring, and network traffic engineering [59,60]. Parallel simulation allows detailed performance analysis faster than real time and thus can be used to predict, control, and fine-tune network parameters in real time. *Real-time network simulation* refers to simulation of large-scale networks in real time so that the virtual network can interact with real implementations of network protocols, network services, and distributed applications. Real-time simulation allows network immersion, where a simulated network is made indistinguishable from a physical network in terms of conducting network traffic between real applications. It provides the necessary realism, scalability, and flexibility for experimental networking research [61].

ADDITIONAL READING

This article is but scratching the surface of the exciting field of PDES. Owing to space limitations, we are far from being able to provide an in-depth review of all the problems and solutions. There are many excellent surveys of the parallel discrete-event simulation field [62–65]. Fujimoto’s book on PDES [66] provides a good review of the intriguing problems and solutions in this area. The Workshop on Principles of Advanced and Distributed Simulation (PADS) is the primary conference for parallel discrete-event

simulation. Many research papers on PDES applications also appear regularly in the Winter Simulation Conference (WSC).

Brunswick, New Jersey

INTRODUCTION

It is important to understand the concept of redundancy in parallel system as it contributes toward improving the reliability of the system. Redundancy is a state where more than one possible ways exists for the system to perform the required operations. When an engineer is designing a system, simply reducing the number of components is not the best strategy. Because in cases where high system reliabilities are needed the engineer must design the system to avoid any single failure and possibly duplicate components to improve the reliabilities, that is, introduce redundancy. And, the common structure of redundancy is the *k-out-of-n* systems where a special case of *k-out-of-n* systems, that is $k = 1$, becomes parallel systems [1,2].

Unlike the series system, in which a single failure of a component results in failure of the whole system, in the parallel system all the elements of the system need to fail to cause failure in operation. As can be seen in Fig. 1 where there are q components connected in parallel such that even if one component fails the link to the other component is still available resulting in successful functioning of the system. In other words, a system is said to be a parallel system if and only if the failure of all components within the system results in the failure of the entire system [3,4]. We study the parallel systems with respect to the warranty policy and also present numerical examples to illustrate the results.

Similar to the case in the series system, the reliability of the parallel system can be expressed as follows: let R_s be the reliability

of the system, $\bar{Z}_i$ be the event of component i that has failed, and $P(\bar{Z}_i)$ be the probability that component i has failed. The reliability of the system is then given by

$$\begin{aligned} R_s &= 1 - P(\bar{Z}_1 \cap \bar{Z}_2 \cap \dots \cap \bar{Z}_q) \\ &= 1 - P(\bar{Z}_1) \cdot P(\bar{Z}_2|\bar{Z}_1) \\ &\quad \times P(\bar{Z}_3|\bar{Z}_1 \cdot \bar{Z}_2) \dots \\ &\quad \times P(\bar{Z}_q|\bar{Z}_1 \cdot \bar{Z}_2 \dots \bar{Z}_{q-1}). \end{aligned} \quad (1)$$

Since the above equation is expressed as a conditional probability, this also includes the case where the previous failure impacts the following failure rates. However, if each component's failure rate is independent, then the equation can be written as

$$\begin{aligned} R_s &= 1 - P(\bar{Z}_1) \cdot P(\bar{Z}_2) \cdot P(\bar{Z}_3) \dots P(\bar{Z}_q) \\ &= 1 - \prod_{i=1}^q P(\bar{Z}_i). \end{aligned} \quad (2)$$

Additionally, for a parallel system, the reliability of the system can be calculated from the reliability of its individual components.

$$R_s = 1 - \prod_{i=1}^q (1 - R_i). \quad (3)$$

We are going to develop the warranty cost model for the parallel system. First, we briefly review the warranty policy. In general, warranty is an obligation attached to products that require the manufacturers to provide compensation for consumers according to the warranty terms when the warranted products fail to perform their intended functions [3]. The warranty is nowadays important not only to the manufacturers but also to the buyers of any commercial product. The consumer is provided a resource for dealing with items that fail due to the uncertainty of product performance. The manufacturer is provided protection because warranty terms explicitly

Figure 1. Parallel system with q components.

limit responsibility in terms of both time and type of product failure.

To develop the cost model for the series system, several assumptions have been made in this article as follows: (i) The repair cost and the replacement cost are constant. (ii) Repair service time and replacement service time are negligible. (iii) All warranty claims are executed and all claims are valid. (iv) Repairs are imperfect and the repair process can be modeled by a quasi-renewal process. (v) The time to perform an inspection in which to determine whether the failed component needs a repair or a replacement is negligible. (vi) The warranty period is renewable.

BACKGROUND

Several researchers [1,5–9] have studied the optimization of system reliability using various techniques and have investigated various characteristics and reliability of the parallel system. Yeh [7] calculates the rate of occurrence of failures of a continuous-time Markov chain and his result is applied to the parallel system. Nakagawa [6] considers the replacement policy for the parallel system in a random environment. Jonkers *et al.* [5] develop the set of machine model building blocks, which is a new algorithm for the prediction of multiple-class parallel section completion times. Asadi and Bayramoglu [1] propose the definition for the mean residual life function of a parallel system and obtain some of its properties. Bairamov *et al.* [8] define the survival and mean residual life

function of a system consisting of n identical and independent components having series or parallel structure. Shen and Xie [9] investigate the effect of such parallel redundancy upon system reliability when applied at various places and in various systems.

We consider that a replacement service would be possible during the warranty period by introducing two alternate quasi-renewal concepts based on the quasi-renewal process. The first is called an *altered quasi-renewal process*. In the quasi-renewal process model, upon each imperfect repair, the time to failure is reduced to a fraction α of the immediately previous one and is dependent on all previous ones. The altered quasi-renewal process, however, does not necessarily have the same patterns. The second is called a *mixed quasi-renewal process* by considering both repairs and replacements subject to imperfect strategies. Using these two alternate quasi-renewal processes, the cost analyses are conducted for a parallel system. For the warranty cost analysis, we obtain a distribution function of the number of failures for the warranty cost analysis, assuming that the warranty policy is renewable.

WARRANTY COST ANALYSIS

In this section, warranty cost analyses are conducted by obtaining the expected warranty cost as well as the variance of the warranty. We also refer to the article titled **Series Systems** in this encyclopedia for the distribution of N to derive several statistical properties of warranty cost function per cycle or per product sold.

Let $f_{ij}(\cdot)$, $F_{ij}(\cdot)$, and $R_{ij}(\cdot)$ be the probability density function (pdf), the cumulative density function (cdf), and reliability function of component j 's failure times after $(i - 1)$ th repair/replacement within a warranty period w , respectively. Additionally, let $f_{is}(\cdot)$, $F_{is}(\cdot)$, and $R_{is}(\cdot)$ be pdf, cdf, and reliability function of system failure times after $(i - 1)$ th repair/replacement within a warranty period w , respectively. β denotes a parameter for altered quasi-renewal process. Using Equation (3), the reliability function

of the j th component and i th failure inter-occurrence interval using the altered quasi-renewal process is as follows:

$$\begin{aligned} R_{is}(w) &= 1 - \prod_{j=1}^q (1 - R_{ij}(w)) \\ &= 1 - \prod_{j=1}^q \left(1 - \left(1 - \int \frac{1}{\beta_{ij}} f_{1j} \left(\frac{1}{\beta_{ij}} x \right) dx \right) \right). \end{aligned} \quad (4)$$

The reliability function for $(n_s + 1)$ th inter-failure interval is

$$\begin{aligned} R_{(n_s+1)s}(w) &= 1 - \prod_{j=1}^q (1 - R_{(n_s+1)j}(w)) \\ &= 1 - \prod_{j=1}^q \left(\int \frac{1}{\beta_{(n_s+1)j}} f_{1j} \left(\frac{1}{\beta_{(n_s+1)j}} x \right) dx \right). \end{aligned} \quad (5)$$

For the cost analysis, we obtain the expected warranty cost function and the variance of the cost function. Let a random variable N_a be the number of repair within a warranty period. Using the pdf of number of failures from the article titled **Series Systems** in this encyclopedia, $f(n_a)$ of the parallel system failure time is given by

$$\begin{aligned} f(n_a) &= \left(\prod_{i=1}^{n_s} (F_{is}(w)) \right) (R_{(n_s+1)s}(w)) \\ &= \left[\left(\prod_{j=1}^q \left(\int f_{1j}(x) dx \right) \right) \right. \\ &\quad \times \prod_{i=2}^{n_s} \left(\prod_{j=1}^q \left(\int \frac{1}{\beta_{ij}} f_{1j} \left(\frac{1}{\beta_{ij}} x \right) dx \right) \right) \Big] \\ &\quad \times \left[1 - \prod_{j=1}^q \left(\int \frac{1}{\beta_{(n_s+1)j}} \right. \right. \\ &\quad \left. \left. \times f_{1j} \left(\frac{1}{\beta_{(n_s+1)j}} x \right) dx \right) \right]. \end{aligned} \quad (6)$$

Using Equation (6), the expected number of warranty repair services is given by

$$E(N_a) = \int n_a \cdot f(n_a) \cdot dn_a. \quad (7)$$

Let r.v. N_b be the number of replacements within a warranty period, respectively. Similar to Equation (7), we obtain the expected number of replacement warranty services:

$$\begin{aligned} E(N_b) &= \int n_b \cdot \left(\prod_{i=1}^{n_b} \left(\int f_{is}(y) dy \right) \right) \\ &\quad \times \left(1 - \int f_{is}(y) dy \right) \cdot dn_b. \end{aligned} \quad (8)$$

Let c_a and c_b be warranty costs for repairs and replacements within a warranty period w respectively. And let C be the warranty system cost for a warranty period w . Eventually, the expected warranty cost for the parallel system is given by

$$E(C) = c_a E(N_a) + c_b E(N_b), \quad (9)$$

where $E(N_a)$ and $E(N_b)$ are given in Equations (7) and (8).

Additionally, using Equations (6) and (7), we can easily derive the second moment as $E(N_a^2) = \int n_a^2 \cdot f(n_a) \cdot dn_a$. Using the first moment and the second moment, the variance of the number of repair services is given by

$$\text{Var}(N_a) = E(N_a^2) - [E(N_a)]^2. \quad (10)$$

Also, the variance in the number of replacement services $\text{Var}(N_b)$ could be obtained by a similar way.

Note that

$$\begin{aligned} E[N_a N_b] &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h n_a n_b \\ &\quad \times P[N_a = n_a, N_b = n_b] \\ &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h n_a n_b P[N_s = n_s] \\ &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h n_a n_b \left(\prod_{i=1}^{n_a+n_b} (F_{is}(w)) \right) \\ &\quad \times (R_{(n_a+n_b+1)s}(w)). \end{aligned} \quad (11)$$

4 PARALLEL SYSTEMS

Using Equations (6) and (11), we also obtain

$$\begin{aligned}
 E[N_a N_b] &= \sum_{n_b=0}^{\infty} \sum_{n_a=0}^h n_a n_b \prod_{j=1}^q \left(\int f_{1j}(x) dx \right) \\
 &\times \prod_{i=2}^{n_a+n_b} \left(\prod_{j=1}^q \left(\int \frac{1}{\beta_{ij}} f_{1j} \left(\frac{1}{\beta_{ij}} x \right) dx \right) \right) \\
 &\times \left[1 - \prod_{j=1}^q \left(\int \frac{1}{\beta_{(n_a+n_b+1)j}} \right. \right. \\
 &\times \left. \left. f_{1j} \left(\frac{1}{\beta_{(n_a+n_b+1)j}} \right) dx \right) \right] \quad (12)
 \end{aligned}$$

Additionally, the covariance of the repair services and the replacement services is given as follows:

$$\text{Cov}(N_a, N_b) = E[N_a N_b] - E[N_a]E[N_b], \quad (13)$$

where $E[N_a], E[N_b]$ are given in Equations (7) and (8) and $E[N_a N_b]$ is given in Equation (12).

Combining Equations (10) and (13), the variance of warranty system cost is given by

$$\begin{aligned}
 \text{Var}(C) &= c_a^2 \cdot \text{Var}(N_a) + c_b^2 \cdot \text{Var}(N_b) \\
 &+ 2c_a c_b \cdot \text{Cov}(N_a, N_b). \quad (14)
 \end{aligned}$$

NUMERICAL EXAMPLES

In this section, a numerical example is presented to illustrate the warranty cost analysis for a two-component parallel system (see Fig. 2). We assume that the failure time of the system follows the exponential distribution with $\lambda = 1$.

Given $q = 2$ and $h = 1$. We assume that the warranty costs and β values are as follows:

$$\begin{aligned}
 c_a &= \$5,000, c_b = \$8,000 \quad \text{and} \\
 \beta_{i1} &= 0.99, \beta_{i2} = 0.98.
 \end{aligned}$$

Figure 2. Parallel system with two components.

The results of the expected warranty cost, $E(C)$, and standard deviation, $SD(C)$, of warranty cost and coefficient of variation (CV) are listed in Table 1 for various values of the warranty period w .

In Fig. 3, the expected warranty cost increases as warranty time increases, which is similar to the plots of the series system. When they are dependent, it can be seen that both the expectation and the standard deviation of warranty cost functions increase monotonically over the warranty period. Furthermore, when they are independent, the CV decreases as the warranty time progresses.

PARALLEL-SERIES AND SERIES-PARALLEL SYSTEMS

INTRODUCTION

In fields such as operations research, engineering, and biostatistics, it is of interest to consider a system where components are connected according to some structure. Two systems that are at the extreme ends of the spectrum are the series system and the parallel system. For a series system, it is necessary for all components to function in order for the system to function. On the other hand, for a parallel system, it only takes one functioning component in order for the system to function. For a more thorough discussion concerning the reliability of these systems, the reader is referred to the articles on *Systems in Series* and *Parallel Configurations*.

A series-parallel system and a parallel-series system are two different systems that result from combining the attributes of a series system and a parallel system. For a series-parallel system, subsystems are connected in series and each subsystem consists of components connected in parallel. The subsystem in a series-parallel system was described in Refs 1 and 2 as a redundant system since the components making up the subsystem can be viewed as similar or redundant components. A subsystem fails only if all of the redundant components have failed, resulting in failure of the main system. In contrast, a parallel-series system consists of subsystems connected in parallel, and each subsystem is made up of components connected in series. Hence, failure of a component in a subsystem results in failure

of the subsystem. However, all subsystems must fail in order for the main system to fail.

One of the earliest papers that considered series-parallel and parallel-series systems is Ref. 3, where a system consisting of m subsystems with each subsystem containing n components was considered. The type of component failure may result in two types of system failure. A component that exhibited a type 1 failure would cause the failure of the subsystem containing the component, while failure of the second type of all components in a subsystem resulted in subsystem failure. Whenever each subsystem has failed due to a type 1 failure, system failure is observed. This is synonymous to the failure of a parallel-series system. On the other hand, a type 2 failure of a single subsystem resulted in system failure. The event is similar to the failure of a series-parallel system. One of the aims in this paper was to find the optimal number of subsystems in order to maximize the probability that the system will function. On the other hand, a special form of a series-parallel system was considered by Boland *et al.* [4] to examine the allocation of a redundant or spare component for a system of n components that functions if $k \leq n$ components function. For such systems, it was shown that in order to optimize system lifetime it is stochastically preferable to place a spare component in parallel to the weakest component.

Majority of the work that dealt with series-parallel or parallel-series systems either investigated the problem of finding the number of components or subsystems required to optimize a given function (e.g., probability that system will function, operational cost associated with system function, etc.) or how to allocate the components in order to make use of the redundant nature of a parallel subsystem. A partial, but not exhaustive, list of papers on finding the number of components or subsystems for a series-parallel or parallel-series system in order to either maximize the probability

of system function or minimize system cost include Refs 5–8. The allocation of components in series-parallel or parallel-series systems via redundancy optimization was also considered, among others, by Elegbede *et al.* [9], Nourelfath and Ait-Kadi [10], Tavakkoli-Moghaddam [11], Wang and Watada [12], and Li *et al.* [13].

In this article, we will obtain the system reliability of a parallel-series system as well as the system reliability of a series-parallel system. Furthermore, we will consider the setting where the reliability of each component is a function of how long a component has been in use.

SYSTEM RELIABILITY

Structure Function

Consider a system of n components, where a component is either in a “functioning” state or in a “failed” state. We will consider the random variables $X_1, \dots, X_n$ assumed to be mutually independent and X_i is a binary random variable such that

$$X_i = \begin{cases} 1, & \text{if component } i \text{ is functioning,} \\ 0, & \text{otherwise.} \end{cases}$$

We will define $\mathbf{X} = (X_1, \dots, X_n)$ to be the state vector of the system. The state of the system is referred to as the *structure function* of the system and is denoted by $\phi(\mathbf{X})$. The function $\phi(\mathbf{X})$ is a binary random variable where

$$\phi(\mathbf{X}) = \begin{cases} 1, & \text{if the system is functioning,} \\ 0, & \text{otherwise.} \end{cases}$$

A primary interest in the study of systems in operations research and reliability is to examine systems, where replacing a failed component by a functioning component does not result in the system being “worse off.” In other words, interest is on systems whose structure functions are nondecreasing. Such a system is called a *coherent system*. For a more thorough discussion of the structure function of a coherent system as well as its properties, the reader is referred to **Coherent Systems**.

Figure 1. Diagram for a parallel-series system with $m = 2$ subsystems and $k = 4$ components per subsystem.

Parallel-Series System

A parallel-series system with mk components where k components are in each of the m subsystems is a system that functions if and only if at least one subsystem is functioning. Thus, the m subsystems form a parallel system. However, within each subsystem, the k components are connected in series so a subsystem will function only if all components are functioning. Figure 1 presents a diagram for a parallel-series system with $m = 2$ subsystems and $k = 4$ components per subsystem.

In order to find the structure function $\phi(\mathbf{X})$ of a parallel-series system, let us first represent the structure function of the j th subsystem by $\phi_j(\mathbf{X}_j)$ for $j = 1, \dots, m$. The vector $\mathbf{X}_j = (X_{j1}, \dots, X_{jk})$ is the state vector of the j th subsystem and X_{ji} is the 0-1 random variable representing the state of the i th component in the j th subsystem, where $X_{ji} = 1$ if component i in subsystem j is functioning. Since the components in a subsystem are connected in series, it follows from the results presented in the **Systems in Series** that the structure function of the j th subsystem is

$$\phi_j(\mathbf{X}_j) = \prod_{i=1}^k X_{ji} = \min(X_{j1}, \dots, X_{jk}). \quad (1)$$

Letting $\mathbf{X} = (\mathbf{X}_1, \dots, \mathbf{X}_m)$ denote the state vector of the system, the structure function of a parallel-series system, following results

presented in **Parallel Configurations**, is

$$\begin{aligned}\phi(\mathbf{X}) &= 1 - \prod_{j=1}^m (1 - \phi_j(\mathbf{X}_j)) \\ &= 1 - \prod_{j=1}^m \left(1 - \left[\prod_{i=1}^k X_{ji} \right] \right).\end{aligned}\quad (2)$$

An alternative representation for the structure function of a parallel-series system is

$$\phi(\mathbf{X}) = \max_{1 \leq j \leq m} \left[\min_{1 \leq i \leq k} X_{ji} \right].$$

As an illustration, consider a parallel-series system with $m = 2$ subsystems and $k = 4$ components per subsystem. If $X_{11} = 0$ and $X_{22} = 0$ while the remaining X_{ji} 's are all equal to 1, then $\phi_1(\mathbf{X}_1) = \min(0, 1, 1, 1) = 0$ and $\phi_2(\mathbf{X}_2) = \min(1, 0, 1, 1) = 0$, resulting in $\phi(\mathbf{X}) = 0$. On the other hand, if $X_{11} = 0$ and $X_{13} = 0$ while the remaining X_{ji} 's are all 1, then $\phi_1(\mathbf{X}_1) = \min(0, 1, 0, 1) = 0$ and $\phi_2(\mathbf{X}_2) = \min(1, 1, 1, 1) = 1$, giving us $\phi(\mathbf{X}) = 1$, a functioning system.

Series-Parallel System

We define a series-parallel system with mk components as a system comprised of m subsystems connected in series and each of the m subsystems consists of k components connected in parallel. From the point of view of failure, a subsystem will fail if all of the components fail, and as soon as one subsystem fails, the series-parallel system will fail. Hence, a subsystem functions if at least one of its k components functions. However, the whole system functions only if all m subsystems function. Using the same notation in the section titled "Parallel-Series System" and using the results in **Parallel Configurations**, the structure function of the j th subsystem is

$$\phi_j(\mathbf{X}_j) = 1 - \prod_{i=1}^k (1 - X_{ji}) = \max(X_{j1}, \dots, X_{jk}).$$

Invoking the results in **Systems in Series**, the structure function of the series-parallel

Figure 2. Diagram for a series-parallel system with $m = 3$ subsystems and $k = 2$ components per subsystem.

system is expressed as

$$\phi(\mathbf{X}) = \prod_{j=1}^m \phi_j(\mathbf{X}_j) = \prod_{j=1}^m \left[1 - \prod_{i=1}^k (1 - X_{ji}) \right].$$

Alternatively, the structure function of the series-parallel system can be written as

$$\phi(\mathbf{X}) = \min_{1 \leq j \leq m} \left[\max_{1 \leq i \leq k} X_{ji} \right].$$

For a concrete example of a series-parallel system, consider a series-parallel system with $m = 3$ subsystems, with each subsystem consisting of $k = 2$ components. An illustration of this system is given in Fig. 2. If $X_{11} = 0, X_{12} = 0$, and $X_{22} = 0$ while the remaining X_{ji} are all equal to 1, then $\phi_1(X_{11}, X_{12}) = \max(0, 0) = 0$, $\phi_2(X_{21}, X_{22}) = \max(1, 0) = 1$, and $\phi_3(X_{31}, X_{32}) = \max(1, 1) = 1$. Thus, one can see that the first subsystem has failed while the remaining subsystems are still functioning. Consequently, $\phi(\mathbf{X}) = \min(0, 1, 1) = 0$, which indicates that the whole system has failed. On the other hand, if $X_{11} = X_{21} = X_{31} = 0$, then $\phi_1(X_{11}, X_{12}) = \max(0, 1) = 1$, $\phi_2(X_{21}, X_{22}) = \max(1, 0) = 1$, and $\phi_3(X_{31}, X_{32}) = \max(0, 1) = 1$; that is, all three subsystems are functioning. Hence, $\phi(\mathbf{X}) = \min(1, 1, 1) = 1$ which shows that the series-parallel system is still functioning.

System Reliability

Consider either a series-parallel system or a parallel-series system that is observed at a specified time instant t . In order to indicate the time-dependence, let $X_{ij}(t)$

indicate the state of the i th component in the j th subsystem at time t . The corresponding state vector of the j th subsystem is $\mathbf{X}_j(t) = (X_{j1}(t), \dots, X_{jk}(t))$. Let $p_{ji}(t) = P\{X_{ji}(t) = 1\}$ be the probability that the i th component in the j th subsystem is functioning at time t , for $j = 1, \dots, m$ and $i = 1, \dots, k$. Let $\mathbf{p}_j(t) = (p_{j1}(t), \dots, p_{jk}(t))$ be the vector of probabilities for subsystem j and $\mathbf{p}(t) = (\mathbf{p}_1(t), \dots, \mathbf{p}_m(t))$ be the vector of probabilities for the m subsystems. The reliability of a system at time t is defined to be

$$h(\mathbf{p}(t)) = P\{\phi(\mathbf{X}(t)) = 1\} = E[\phi(\mathbf{X}(t))].$$

The random variables $X_{ji}(t)$ s are independent. To find the reliability of a parallel-series system, we first note that the probability that the j th subsystem is functioning at t is

$$\begin{aligned} P\{\phi_j(\mathbf{X}_j(t)) = 1\} &= P\{\min(X_{j1}(t), \dots, X_{jk}(t)) = 1\} \\ &= P\{X_{j1}(t) = 1, \dots, X_{jk}(t) = 1\} \\ &= \prod_{i=1}^k p_{ji}(t). \end{aligned} \quad (3)$$

On the other hand, the probability that the system is functioning at time t is equal to the probability that at least one subsystem is functioning at that time instant. Owing to the fact that $\phi(\mathbf{X}(t))$ is either 0 or 1, it follows that $h(\mathbf{p}(t)) = 1 - P\{\phi(\mathbf{X}(t)) = 0\}$. Since the subsystems will also be mutually independent, then

$$\begin{aligned} h(\mathbf{p}(t)) &= 1 - P\{\phi_1(\mathbf{X}_1(t)) = 0, \dots, \phi_m(\mathbf{X}_m(t)) = 0\} \\ &= 1 - \prod_{j=1}^m P\{\phi_j(\mathbf{X}_j(t)) = 0\}. \end{aligned} \quad (4)$$

Combining Equations (3) and (4), the reliability of a parallel-series system is

$$\begin{aligned} h(\mathbf{p}(t)) &= 1 - \prod_{j=1}^m [1 - P\{\phi_j(\mathbf{X}_j(t)) = 1\}] \\ &= 1 - \prod_{j=1}^m \left[1 - \prod_{i=1}^k p_{ji}(t) \right]. \end{aligned} \quad (5)$$

For a series-parallel system, we note that since the components in a subsystem are connected in parallel, then

$$\begin{aligned} P\{\phi_j(\mathbf{X}_j(t)) = 1\} &= 1 - P\{\phi_j(\mathbf{X}_j(t)) = 0\} \\ &= 1 - P\left\{ \bigcup_{i=1}^k (X_{ji}(t) = 0) \right\}. \end{aligned}$$

Since components are mutually independent, it follows that

$$\begin{aligned} P\{\phi_j(\mathbf{X}_j(t)) = 1\} &= 1 - P\{X_{j1}(t) = 0\} \cdots \\ &\quad \times P\{X_{jk}(t) = 0\} \\ &= 1 - \prod_{i=1}^k (1 - p_{ji}(t)). \end{aligned} \quad (6)$$

Furthermore, the subsystems are connected in series which results in

$$\begin{aligned} h(\mathbf{p}(t)) &= P\{\phi_1(\mathbf{X}_1(t)) = 1, \dots, \phi_m(\mathbf{X}_m(t)) = 1\} \\ &= \prod_{j=1}^m P\{\phi_j(\mathbf{X}_j(t)) = 1\}. \end{aligned} \quad (7)$$

Thus, using Equations (6) and (7), the reliability of a series-parallel system at time t is obtained to be

$$\begin{aligned} h(\mathbf{p}(t)) &= \left[1 - \prod_{i=1}^k (1 - p_{1i}(t)) \right] \cdots \\ &\quad \times \left[1 - \prod_{i=1}^k (1 - p_{mi}(t)) \right] \\ &= \prod_{j=1}^m \left[1 - \prod_{i=1}^k (1 - p_{ji}(t)) \right]. \end{aligned} \quad (8)$$

We can generalize the notion of the state of a component by considering the random variable T_{ji} to denote the lifetime of the component i in subsystem j , $j = 1, \dots, m$ and $i = 1, \dots, k$, where $f_{ji}(t; \theta)$ is the corresponding probability density function that is parameterized by some parameter vector θ . From Ref. 14, the probability that this component is functioning at time t is

$$p_{ji}(t; \theta) \equiv P\{T_{ji} > t\} = \int_t^\infty f_{ji}(u; \theta) du. \quad (9)$$

For a parallel-series system, we define the lifetime of subsystem j by Y_j and the lifetime of the system by Y . From Equation (1), we get $Y_j = \min(T_{j1}, \dots, T_{jk})$ and while using Equation (2), we obtain $Y = \max(Y_1, \dots, Y_m)$. Since the component lifetimes are independent and $P\{Y_j > t\} = \prod_{i=1}^k P\{T_{ji} > t\}$, the system reliability in Equation (5) simplifies to

$$\begin{aligned} h(\mathbf{p}(t; \theta)) &= 1 - \prod_{j=1}^m \left[1 - \prod_{i=1}^k P\{T_{ji} > t\} \right] \\ &= 1 - \prod_{j=1}^m \left[1 - \prod_{i=1}^k p_{ji}(t; \theta) \right]. \end{aligned} \quad (10)$$

For a series-parallel system, the lifetime of the j th subsystem is $Y_j = \max(T_{j1}, \dots, T_{jk})$ and the resulting system lifetime is $Y = \min(Y_1, \dots, Y_m)$. Since

$$\begin{aligned} P\{Y_j > t\} &= 1 - P\{\max(T_{j1}, \dots, T_{jk}) \leq t\} \\ &= 1 - \prod_{i=1}^k P\{T_{ji} \leq t\}, \end{aligned}$$

it follows from Equation (8) that the reliability of a series-parallel system at time t is

$$\begin{aligned} h(\mathbf{p}(t; \theta)) &= \prod_{j=1}^m \left[1 - \prod_{i=1}^k P\{T_{ji} \leq t\} \right] \\ &= \prod_{j=1}^m \left[1 - \prod_{i=1}^k [1 - p_{ji}(t; \theta)] \right]. \end{aligned} \quad (11)$$

NUMERICAL EXAMPLE

As an illustration, consider the case when each component lifetime follows an exponential distribution with mean $1/\lambda_{ji}$, that is, $T_{ji} \sim \text{EXP}(\lambda_{ji})$. Hence, the random variable T_{ji} has density function

$$f_{ji}(t; \lambda_{ji}) = \lambda_{ji} \exp(-\lambda_{ji} t), \quad \lambda_{ji} > 0, \quad t > 0.$$

A partial list of papers that considered the exponential distribution for series-parallel or parallel-series systems include Refs 8 and 15–18. For further discussion

regarding the exponential distribution, the reader is referred to **Systems in Series**.

Using Equation (9), the probability that component i in the j th subsystem is functioning at time t is

$$\begin{aligned} p_{ji}(t; \lambda_{ji}) &= \int_t^\infty \lambda_{ji} \exp(-\lambda_{ji} u) du \\ &= \exp(-\lambda_{ji} t). \end{aligned} \quad (12)$$

Let $\lambda = (\lambda_{11}, \dots, \lambda_{1k}, \lambda_{21}, \dots, \lambda_{2k}, \dots, \lambda_{m1}, \dots, \lambda_{mk})$ be the vector of parameters. For a parallel-series system, the system reliability given in Equation (10) simplifies to

$$\begin{aligned} h(\mathbf{p}(t; \lambda)) &= 1 - \prod_{j=1}^m \left[1 - \prod_{i=1}^k \exp(-\lambda_{ji} t) \right] \\ &= 1 - \prod_{j=1}^m \left[1 - \exp\left(-\sum_{i=1}^k \lambda_{ji} t\right) \right]. \end{aligned}$$

On the other hand, using Equations (11) and (12), the reliability of a series-parallel system is obtained to be

$$h(\mathbf{p}(t; \lambda)) = \prod_{j=1}^m \left[1 - \prod_{i=1}^k (1 - \exp(-\lambda_{ji} t)) \right].$$

As a special case, suppose $T_{ji} \sim \text{EXP}(\beta)$, that is, component lifetimes are independent and identically distributed with mean $1/\beta$. The system reliability of a parallel-series system simplifies to

$$h(\mathbf{p}(t; \beta)) = 1 - [1 - \exp(-k(\beta t))]^m,$$

while the system reliability of a series-parallel system simplifies to

$$h(\mathbf{p}(t; \beta)) = [1 - (1 - \exp(-\beta t))^k]^m.$$

PARAMETRIC LP ANALYSIS

ALLEN HOLDER
Department of Mathematics,
Rose-Hulman Institute of
Technology, Terre Haute,
Indiana

The study of parametric linear programming dates back to the work of Gass and Saaty [1], Mills [2] and Saaty and Gass [3] in the middle 1950s (see also Refs 4–6). The analysis of how optimal properties depend on a problem's data is important since it allows a model to be used for its intended purpose of explaining the underlying phenomena. This is because models are often constructed with imperfect information, and the study of parametric and sensitivity analysis relates optimal properties to the problem's data description. The topic is a mainstay in introductory texts on operations research and linear programming. Here we advance the typical introduction and point to some modern applications. For the sake of brevity we omit proofs and instead cite publications in which proofs can be located.

We assume the standard form primal and dual throughout,

$$(LP) \min\{c^T x : Ax = b, x \geq 0\} \text{ and}$$

$$(LD) \max\{b^T y : A^T y + s = c, s \geq 0\},$$

where $A \in \mathbb{R}^{m \times n}$ has full row rank, $b \in \mathbb{R}^m$, and $c \in \mathbb{R}^n$. For any $B \subseteq \{1, 2, \dots, n\}$ we let A_B be the submatrix of A whose column indices are in B . We further let $N = \{1, 2, \dots, n\} \setminus B$ so that A_N contains the columns of A not in A_B . Similarly, c_B and c_N denote the subvectors of c whose components are in the set subscripts. The partition (B, N) is *optimal* if both

$$A_B x_B = b, x_B \geq 0 \text{ and}$$

$$A_B^T y = c_B, A_N^T y + s_N = c_N, s_N \geq 0 \quad (1)$$

are consistent. One special case is if A_B is invertible, and we refer to such a partition as

basic or as a *basis*. If a basis is optimal, the above systems can be expressed as

$$A_B^{-1}b \geq 0 \text{ and } c_N - A_N^T(A_B^T)^{-1}c_B \geq 0. \quad (2)$$

Another special case is if B is *maximal*, meaning that it is not contained in another optimal B . There is a unique maximal B for any A , b , and c , and we denote the corresponding partition as $(\hat{B}, \hat{N})$. This fact was first established in Ref. 7. We mention that the terminology used here differs from that in some of the supporting literature. The maximal partition is often called the *optimal partition*, but since it is generally only one of many optimal partitions, we distinguish it with the term *maximal* since this is the mathematical property it has in relation to the other optimal partitions. An optimal solution to (LP) and (LD) can be constructed for any optimal (B, N) by letting y , x_B , and s_N be any solution to Equation (1) and by letting $x_N = 0$ and $s_B = 0$.

The classical study in parametric analysis considers linear changes in one of b or c , and it is this case that we primarily study. Let $\mathcal{B} \in \mathbb{R}^m$ and consider the parametrized linear program

$$z^*(\theta) = \min\{c^T x : Ax = b + \theta\mathcal{B}, x \geq 0\}.$$

A typical question is, "Over what range of θ does an optimal basis remain optimal?" Since the dual inequality in Equation (2) is unaffected by a change in b , we have that a basic optimal solution remains optimal so long as

$$x_B(\theta) = A_B^{-1}(b + \theta\mathcal{B}) \geq 0.$$

Hence the basis remains optimal as long as θ is at least

$$\begin{aligned} & \max \left\{ -[A_B^{-1}b]_i / \mathcal{B}_i : \mathcal{B}_i > 0 \right\} \\ & = \min \{ \theta : A_B x_B = b + \theta\mathcal{B}, x \geq 0, x_N = 0 \} \end{aligned} \quad (3)$$

and at most

$$\begin{aligned} & \min \left\{ -[A_B^{-1}b]_i / \mathcal{B}_i : \mathcal{B}_i < 0 \right\} \\ & = \max \{ \theta : A_B x_B = b + \theta \mathcal{B}, x \geq 0, x_N = 0 \}. \end{aligned} \quad (4)$$

The left-hand side of these two equalities is a common ratio test, but it is insightful to realize that these equate to the stated linear programs. The objective value's response over this range is

$$z^*(\theta) = c_B^T x_B(\theta) = c_B^T A_B^{-1} b + \theta c_B^T \mathcal{B},$$

which shows that the objective function is linear as long as the basis remains optimal.

The above calculation is often used to support the result that $z^*(\theta)$ is continuous, piecewise linear, and convex. Although true, the above analysis of a basic optimal solution does not immediately lead to a characterization of z^* since bases need not remain optimal as long as z^* is linear. As an illustration, we consider the following example throughout,

$$A = \begin{bmatrix} 1 & 1 & -1 & 0 \\ 0 & 1 & 0 & -1 \end{bmatrix}, \quad b = \begin{pmatrix} 1 \\ 3 \end{pmatrix},$$

$$\mathcal{B} = \begin{pmatrix} 0 \\ -1 \end{pmatrix} \text{ and } c = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \end{pmatrix}.$$

The unique optimal basis for $\theta = 0$ is $B = \{2, 3\}$, and this basis remains optimal as long as $0 \leq \theta \leq 2$. However, for $2 < \theta < 3$ the unique optimal basis is $B = \{1, 2\}$, and we have

$$x_B(\theta) = x_B(0) + \theta A_B^{-1} \mathcal{B} = \begin{pmatrix} -2 \\ 3 \end{pmatrix} + \theta \begin{pmatrix} 1 \\ -1 \end{pmatrix}.$$

For $\theta > 3$ the unique optimal basis is $\{1, 4\}$, and

$$x_B(\theta) = x_B(0) + \theta A_B^{-1} \mathcal{B} = \begin{pmatrix} 1 \\ -3 \end{pmatrix} + \theta \begin{pmatrix} 0 \\ 1 \end{pmatrix}.$$

For these three bases we have

$$B = \{2, 3\} \Rightarrow c_B^T A_B^{-1} \mathcal{B} = -1$$

$$B = \{1, 2\} \Rightarrow c_B^T A_B^{-1} \mathcal{B} = -1$$

$$B = \{1, 4\} \Rightarrow c_B^T A_B^{-1} \mathcal{B} = 0,$$

and the objective value is

$$z^*(\theta) = \begin{cases} 3 - \theta, & 0 \leq \theta \leq 3 \\ 0, & \theta > 3. \end{cases}$$

The *linearity intervals* of z^* are $[0, 3]$ and $[3, \infty)$, and over the interior of the first we have $dz^*/d\theta = -1$ and over the interior of the second we have $dz^*/d\theta = 0$. This example shows that a linearity interval is not necessarily identified from the initial collection of optimal bases, that is, no basis that is optimal for $\theta = 0$ remains optimal over the first linearity interval. The intersection of two adjoining linearity intervals is called a *break point*, and two linearity intervals sharing a break point are said to *adjoin*. Although the objective z^* is not differentiable at a break point, the left and right derivatives exist as long as feasibility is possible on both sides of the break point. Additional examples of this behavior are found in Ref. 8.

The observation that no basis is guaranteed to remain optimal over a linearity interval leads to the question of how to characterize the behavior of the objective value under parametrization. One solution to this question was motivated by the advent of interior-point methods in the 1980s and 1990s. Specifically, we consider the optimal solution that is the limit of the central path. The central path is the collection of unique solutions to

$$Ax = b, \quad x > 0, \quad A^T y + s = c, \quad s > 0,$$

$$x_i s_i = \mu > 0, \quad \forall i,$$

which we denote by the parametrization $(x(\mu), y(\mu), s(\mu))$. The path converges as $\mu \downarrow 0$ to a unique optimal solution (x^*, y^*, s^*) up to the representation of the problem defined by A , b , and c . This solution induces $(\hat{B}, \hat{N})$ as follows:

$$\hat{B} = \{i : x_i^* > 0\} \text{ and } \hat{N} = \{i : x_i^* = 0\}.$$

The solution x^* is continuous with respect to b [9], which immediately implies $z^*(\theta)$ is continuous in θ .

Returning to the example, we have $\hat{B} = \{1, 2, 3\}$ for $0 \leq \theta < 3$, since each variable indexed by this set can be positive

in an optimal solution. For example, $x^*(\theta) = (5, 3 - \theta, 7 - \theta, 0)$ is optimal over this range. The variable x_2 is forced to zero once θ reaches 3, and the maximal partition changes to $\hat{B} = \{1, 3\}$ and $\hat{N} = \{2, 4\}$. For $\theta > 3$, the maximal partition is $\hat{B} = \{1, 4\}$ and $\hat{N} = \{2, 3\}$. This suggests that the maximal partition remains constant over the interior of each linearity interval. This is indeed true, and an analysis based on the maximal partition characterizes $z^*(\theta)$ since it algebraically describes the optimal sets of (LP) and (LD), which are respectively

$$\mathcal{P}^* = \{x : Ax = b, x \geq 0, x_{\hat{N}} = 0\} \quad \text{and} \\ \mathcal{D}^* = \{(y, s) : A^T y + s = c, s_{\hat{B}} = 0\}.$$

The counterparts to the right-hand sides of Equations (3) and (4) are to solve

$$\min \{\theta : Ax = b + \theta \mathcal{B}, x \geq 0, x_{\hat{N}} = 0\} \quad \text{and} \\ \max \{\theta : Ax = b + \theta \mathcal{B}, x \geq 0, x_{\hat{N}} = 0\}.$$
 (5)

As long as θ is between these optimal values, the objective z^* is linear, and the derivative of z^* over the interior of this range is

$$D = \max\{\mathcal{B}^T y : A^T y + s = c, s \geq 0, s_{\hat{B}} = 0\},$$
 (6)

which is a solution to a linear program defined over the dual optimal set. For the example, the optimal value of this math program is -1 for $\hat{B} = \{1, 2, 3\}$, which is the maximal partition for $0 < \theta < 3$ and is 0 for $\hat{B} = \{1, 4\}$, which is the maximal partition for $3 < \theta$.

The linear programs in Equations (5) and (6) are stated in terms of $(\hat{B}, \hat{N})$, and although mathematically correct, these sets are non-trivial to calculate due to numerical round-off, presolving, and scaling. An alternative is to replace the linear programs in Equations (5) and (6) with

$$\min \{\theta : Ax = b + \theta \mathcal{B}, x \geq 0, c^T x = z^*(0) + \theta D\}, \\ \max \{\theta : Ax = b + \theta \mathcal{B}, x \geq 0, c^T x = z^*(0) + \theta D\}, \\ \text{and} \\ \max\{\mathcal{B}^T y : A^T y + s = c, s \geq 0, b^T y = z^*(0)\}.$$

The equalities guaranteeing optimality can further be relaxed to $c^T x \leq z^*(0) + \theta D + \varepsilon$ and $b^T y \geq z^*(0) - \varepsilon$ to improve numerical stability if needed, where the parameter ε approximates the numerical tolerance of zero.

Results under the parametrization $c + \lambda \mathcal{C}$ mirror those for the right-hand side parametrization; the main difference being that the roles of the primal and dual reverse. In this case, we indicate the dependence on λ by using $z^*(\lambda)$ instead of $z^*(\theta)$. The following theorem presents the results for changes in one of θ or λ . See Refs 10–15 for various proofs.

Theorem 1. *Let $\mathcal{B}$ and $\mathcal{C}$ be directions of perturbation for b and c , and let $(\hat{B}, \hat{N})$ be the maximal partition for the unperturbed linear programs. Then the following hold:*

1. $(\hat{B}, \hat{N})$ remains the unique maximal partition under the parametrization $b + \theta \mathcal{B}$ as long as

$$\theta^- = \min\{\theta' : Ax = b + \theta' \mathcal{B}, x \geq 0, \\ x_{\hat{N}} = 0\} \\ < \theta < \max\{\theta' : Ax = b + \theta' \mathcal{B}, \\ x \geq 0, x_{\hat{N}} = 0\} = \theta^+,$$

provided that one of θ^- or θ^+ is nonzero.

2. Either $\theta^- = \theta^+ = 0$ or $\theta^- < 0 < \theta^+$.
3. The largest interval containing zero over which $z^*(\theta)$ is linear is $[\theta^-, \theta^+]$.
4. The dual optimal set, $\{(y, s) : A^T y + s = c, s \geq 0, s_{\hat{B}} = 0\}$, is invariant for $\theta \in (\theta^-, \theta^+)$, provided that θ^+ and θ^- are nonzero.
5. Assume θ^- and θ^+ are nonzero. Let $(\hat{B}', \hat{N}')$ and $(\hat{B}'', \hat{N}'')$ be the respective maximal partitions for $\theta = \theta^-$ and $\theta = \theta^+$. Then, $\hat{B}' \subset \hat{B}$, $\hat{N}' \supset \hat{N}$, $\hat{B}'' \subset \hat{B}$, and $\hat{N}'' \supset \hat{N}$.
6. If θ^- and θ^+ are nonzero and $\theta \in (\theta^-, \theta^+)$, then

$$\frac{dz^*(\theta)}{d\theta} = \max\{\mathcal{B}^T y : A^T y + s = c, s \geq 0, \\ s_{\hat{B}} = 0\}.$$

7. $(\hat{B}, \hat{N})$ remains the unique maximal partition under the parametrization $c + \lambda \hat{c}$ as long as

$$\begin{aligned} \lambda^- &= \min\{\lambda' : A^T y + s = c + \lambda' \hat{c}, s \geq 0, \\ &\quad s_{\hat{B}} = 0\} \\ &< \lambda < \max\{\lambda' : A^T y + s = c + \lambda' \hat{c}, \\ &\quad s \geq 0, s_{\hat{B}} = 0\} = \lambda^+, \end{aligned}$$

provided that one of λ^- or λ^+ is nonzero.

8. Either $\lambda^- = \lambda^+ = 0$ or $\lambda^- < 0 < \lambda^+$.
9. The largest interval containing zero over which $z^*(\lambda)$ is linear is $[\lambda^-, \lambda^+]$.
10. The primal optimal set, $\{x : Ax = b, x \geq 0, x_{\hat{N}} = 0\}$, is invariant for $\lambda \in (\lambda^-, \lambda^+)$, provided that λ^- and λ^+ are nonzero.
11. Assume λ^- and λ^+ are nonzero. Let $(\hat{B}', \hat{N}')$ and $(\hat{B}'', \hat{N}'')$ be the respective maximal partitions for $\lambda = \lambda^-$ and $\lambda = \lambda^+$. Then, $\hat{B}' \supset \hat{B}$, $\hat{N}' \subset \hat{N}$, $\hat{B}'' \supset \hat{B}$, and $\hat{N}'' \subset \hat{N}$.
12. If λ^- and λ^+ are nonzero and $\lambda \in (\lambda^-, \lambda^+)$, then

$$\begin{aligned} \frac{dz^*(\lambda)}{d\lambda} &= \min\{\hat{c}^T x : Ax = b, x \geq 0, \\ &\quad x_{\hat{N}} = 0\}. \end{aligned}$$

Theorem 1 states that the maximal partition characterizes the linearity of z^* about $\theta = 0$. Compared to the basis approach in Equations (3) and (4), the calculation guaranteeing the identification of the entire linearity interval requires the solution of two linear programs. Theorem 1 also distinguishes the roles of the primal and dual. The fourth and tenth statements show that one of the primal or the dual optimal sets is invariant over the interior of a linearity interval. For example, under the parametrization of b the dual optimal set remains intact, and hence, any basis within the maximal partition corresponds to a vertex of the dual optimal set independent of the θ in (θ^-, θ^+) . Similarly, as c is parametrized over the interior of its linearity interval, the primal optimal set is unchanged, and any basis within the maximal partition corresponds to a vertex of the primal optimal set. To be precise, let

(B, N) be any optimal partition for $\theta = 0$, for which there is a dual optimal solution (y, s) so that

$$A^T y + s = c, s \geq 0, s_B = 0.$$

Assuming that θ^- and θ^+ are nonzero, we have from Theorem 1 that if $\theta \in (\theta^-, \theta^+)$, then there is a primal solution x such that

$$Ax = b + \theta \hat{b}, x \geq 0, x^T s = 0.$$

In the case that (B, N) is basic, we say that the basis is *dual optimal* for $\theta \in (\theta^-, \theta^+)$. Similarly, if c is parametrized, then for any x such that

$$A_B x_B = b, x \geq 0, x_N = 0,$$

we know that there are y and s so that

$$A^T y + s = c + \lambda \hat{c}, s \geq 0, x^T s = 0,$$

provided that $\lambda \in (\lambda^-, \lambda^+)$. Again, if (B, N) is basic, we say that the basis is *primal optimal* for $\lambda \in (\lambda^-, \lambda^+)$.

The interplay between the basic and the maximal partitions is of special interest at a break point. As an illustration, consider the example for $\theta = 3$. There are two optimal basic partitions, which we denote by $(B', N') = (\{1, 2\}, \{3, 4\})$ and $(B'', N'') = (\{1, 4\}, \{2, 3\})$. The maximal partition is $(\hat{B}, \hat{N}) = (\{1, 3\}, \{2, 4\})$. In this case we have

$$\begin{aligned} 0 &= \min\{\theta : Ax = b + (3 + \theta)\hat{b}, x \geq 0, x_{\hat{N}} = 0\} \\ &= \max\{\theta : Ax = b + (3 + \theta)\hat{b}, x \geq 0, x_{\hat{N}} = 0\}. \end{aligned}$$

This shows the linearity interval for the perturbed right-hand side of $b + 3\hat{b}$ is the singleton $[0, 0] = \{0\}$, and we say that the maximal partition is *incompatible* with parametrizations away from $b + 3\hat{b}$ along $\hat{b}$. However, the basic optimal partitions give

$$\begin{aligned} -1 &= \min\{\theta : Ax = b + (3 + \theta)\hat{b}, x \geq 0, x_{N'} = 0\} \\ 0 &= \max\{\theta : Ax = b + (3 + \theta)\hat{b}, x \geq 0, x_{N'} = 0\} \end{aligned} \tag{7}$$

and

$$0 = \min\{\theta : Ax = b + (3 + \theta)\mathcal{B}, x \geq 0, x_{N''} = 0\}$$

$$\infty = \max\{\theta : Ax = b + (3 + \theta)\mathcal{B}, x \geq 0, x_{N''} = 0\}.$$

So (B', N') is *compatible* with $\mathcal{B}$ as θ decreases and (B'', N'') is *compatible* with $\mathcal{B}$ as θ increases. In the case of θ decreasing we note that (B', N') does not identify the entire linearity interval. If θ increases, then the last linear program being unbounded shows that the linearity interval is unbounded. From the example we see that different partitions are compatible with different directions of perturbation. A theory of compatibility is developed in Refs 12 and 16.

Combining Theorem 1 with the study of what occurs at a break point gives a complete analysis of z^* as either θ or λ traverse through all possible values for which the primal and dual are feasible, in which case the parameters could move through multiple linearity intervals. The question that remains is how to move from one linearity interval, through a break point, and to the adjoining interval. From the above example we see that we can always move into a linearity interval with a basis, even from a break point. However, identifying a compatible basis in a degenerate problem is not simple. From Theorem 1 we see that the maximal partition provides a definitive technique that rests on solving a linear program. Suppose the maximal partition $(\hat{B}, \hat{N})$ is incompatible with $\mathcal{B}$, a fact that would be known upon calculating θ^+ to be zero in the first statement of Theorem 1. The adjoining linearity interval is of the form $[0, \theta']$, where $\theta' > 0$. We let $(\hat{B}', \hat{N}')$ be the unique maximal partition for $\theta \in (0, \theta')$. To find $(\hat{B}', \hat{N}')$ we solve

$$\max\{\mathcal{B}^T y : A^T y + s = c, s \geq 0, s_{\hat{B}} = 0\}.$$

From Ref. 10 we have that

$$\hat{B}' = \{i : s_i = 0 \text{ for all optimal } (y, s)\} \text{ and}$$

$$\hat{N}' = \{1, 2, \dots, n\} \setminus B''. \quad (8)$$

Subsequently, we have from the fifth and sixth statements of Theorem 1 that the solution to this problem is the right-sided derivative of z^* at $\theta = 0$.

The change in the maximal partition denoted in Equation (8) leads to the following algorithm to calculate z^* . As with Equations (5) and (6) the linear programs can be stated in terms of the objective function for stability reasons, and it is this presentation that we use.

1. Calculate $z^*(0) = \min\{c^T x : Ax = b, x \geq 0\}$ and initialize θ^- to be zero.
2. Calculate $D^+ = \max\{\mathcal{B}^T y : Ay + s = c, s \geq 0, b^T y = z^*(\theta^-)\}$. If the problem is unbounded, then stop.
3. Calculate $\max\{\theta : Ax = b + \theta\mathcal{B}, x \geq 0, c^T x = z^*(\theta^-) + \theta D^+\}$ and let θ^+ be the optimal value (possibly infinity). Note that we always have $\theta^- < \theta^+$ since we are moving through a linearity interval.
4. Let $z^*(\theta) = z^*(\theta^-) + \theta D^+$ for either $\theta \in (\theta^-, \theta^+]$, if $\theta^+ < \infty$, or $\theta \in (\theta^-, \theta^+)$, if $\theta^+ = \infty$.
5. If $\theta^+ < \infty$, then let $\theta^- = \theta^+$ and return to step 3. Otherwise, stop.

We only state the algorithm for parametrizations in b . The algorithm for changes in c is analogous.

The study of parametrizations in one of b or c naturally continues with questions of simultaneous changes in b and c . In fact, the general question is to study the essence of optimality as the data (A, b, c) is parametrized along $(\mathcal{A}, \mathcal{B}, \mathcal{C})$. An expanded study of this topic is beyond the scope of this article, and we point readers to the bibliography, which includes works outside those cited in support of a continued study. One result from Ref. 12 is particularly germane to our discussion of characterizing z^* . Consider what happens if A remains constant and b and c change simultaneously. In this situation we are interested in

$$z^*(\theta) = \min\{(c + \theta\mathcal{C})^T x : Ax = b + \theta\mathcal{B}, x \geq 0\}.$$

Let (x^*, y^*, s^*) be a primal-dual solution for $\theta = 0$ such that $x_B^* > 0$ and $s_N^* > 0$. As long as $\mathcal{B}$ and $\mathcal{C}$ are compatible with $(\hat{B}, \hat{N})$, we have

that

$$z^*(\theta) = z(0) + \theta \left(\bar{x}_B x_B^* + \bar{y}_N^T y_N \right) + \theta^2 \left(\bar{x}_B A_B^+ \bar{y}_N \right),$$

where A_B^+ is any generalized inverse of A_B . The first-order term is the sum of the primal and dual derivatives for the case in which they are parametrized individually. The second-order term shows that the curvature of z^* is $\bar{x}_B A_B^+ \bar{y}_N$, which is invariant with respect to the choice of the generalized inverse.

Parametric linear programming has been used outside of typical query questions of the type “What if ...?” Parametric analysis on matching problems has been used in Ref. 17 to identify undesirable job assignments for the US Navy. It was also used in Ref. 18 to design a regional network for efficient and equitable liver allocation, and in Ref. 19 to prune radiotherapy treatments by restricting the search space. Each of these applications is based on the fact that the collection of Pareto optimal solutions to a bi-objective linear programming problem can be expressed parametrically. For example, consider the bi-objective linear program

$$\min \left\{ \begin{pmatrix} c^T x \\ d^T x \end{pmatrix} : Ax = b, x \geq 0 \right\}.$$

Owing to the convexity of the problem we know that each Pareto optimal solution is also a solution to

$$\min\{(c + \lambda(d - c))x : Ax = b, x \geq 0\},$$

for some, not necessarily unique, $\lambda \in (0, 1)$ [20]. The analysis above shows that we can calculate the linearity intervals of this problem and the rate at which the objective value changes over each linearity interval by solving a series of linear programs. If we let (B^k, N^k) be the finite sequence of maximal partitions at the break points in $(0, 1)$, then any variable whose index is not in

$$\bigcup_k B^k$$

is zero in every Pareto solution. This conveniently allows us to mathematically identify

the variables that can be removed without altering the Pareto set. This works only for the bi-objective case, which somewhat limits its applicability. A host of related applications is found in Ref. 21.

PARTIALLY OBSERVABLE MDPS (POMDPS): INTRODUCTION AND EXAMPLES

EMINE YAYLALI

JULIE S. IVY

Edward P. Fitts Department of Industrial
and Systems Engineering, North Carolina
State University, Raleigh, North Carolina

A Markov decision process (MDP) is an optimization model used for sequential decision making in a stochastic environment. The theory, applications, and solution techniques for MDPs have been investigated in several papers and books [1,2]. The objective of an MDP model is often to determine a set of decision rules called *policy* for selecting an appropriate *action* in every *decision epoch*. A key assumption of Markov models is that the transition probability from the current state of the system to the state of the system at next decision epoch depends only on the current state, and not on the prior states or actions of the system. Any stochastic dynamic system that satisfies this Markovian property becomes a controlled Markov process when the transition probabilities can be affected by the decision maker's actions. MDPs and partially observable Markov decision processes (POMDPs) are the examples of the controlled Markov processes. In the MDP framework, the state of the system is assumed to be completely observable by decision maker with the help of perfect observations (and hence known with certainty by the decision maker). Relaxation of this assumption yields a POMDP or a hidden Markov chain (HMC). In the case of HMCs, the underlying stochastic system is hidden and assumed to be Markov based on observations that signal the system's hidden states. Similarly, the underlying state of the POMDP is determined through a sequence of observations. However, in a POMDP, the decision maker can affect the transition of the system through the selection of actions. This is the key

difference between a POMDP and an HMC. Table 1, which was proposed by Littman, best illustrates these distinctions [3].

A POMDP is a generalization of MDPs in which there is incomplete information and uncertainty regarding the current state of the Markov process. Incomplete information regarding the state of process affects the optimal choice of actions. Physical constraints, noise-corrupted readings in the observation of state, or simply being too costly to observe state can result in uncertainty. Some examples for which the uncertainty of the state is a realistic key assumption include machine maintenance, learning theory, artificial intelligence, and health care. Shiryaev [4] initially formulated a detection problem with random process whose parameters were unknown and explored applying a Markov process as a special case of this problem. Drake, Astrom and Sondik later defined explicit formulations for a POMDP [5–7]. Since then, the theory of POMDPs including solution techniques and structural characteristics has been an active research topic.

The generalization of an MDP to a POMDP increases computational complexity by adding dimensionality due to the uncertainty of states (depending on the definition of the MDP state space this uncertainty can add several dimensions to the state space). In comparison to MDPs, POMDPs have an infinite state space. Furthermore, an optimal policy for a POMDP is defined over a continuous state space. These features of a POMDP increase the computational effort and memory required to solve the model optimally. Typical exact solution procedures for a POMDP rely on dynamic programming approaches and often are insufficient for solving real-world problems because of the computational burden (i.e., the curse of dimensionality). Research on efficient algorithms to solve POMDPs varies from exact algorithms [7–12] to approximation methods. Finite-memory, finite-grid approximations, and heuristics for developing feasible bounds are examples of approximate solution

techniques for POMDPs [13,14]. For detailed information, see Lovejoy’s and White’s surveys on solution techniques [15,16].

The remainder of this article is organized as follows: the section titled “Partially Observable Markov Decision Processes” presents a general formulation for a POMDP and the section titled “Applications of POMDP” summarizes several applications of POMDPs.

PARTIALLY OBSERVABLE MARKOV DECISION PROCESSES

A POMDP is completely characterized by $\langle S, A, Z, P, Q, R \rangle$: the core state space, the action space, the set of observations, the transition probability matrix, the information matrix, and the reward function. Each of the elements of a POMDP model is discussed in detail the following sections.

Core States

Let $\{s(t), t = 0, 1, \dots\}$ be the *core state* of the system at *decision epoch*, t . For simplicity in presentation, $s(t)$ is assumed to be a finite state discrete-time Markov chain with stationary transition probability matrix $P = [p_{ij}]$, $i, j \in S$ where S is called *core state space*. The transition probability matrix P completely defines the core process; however, decision maker cannot directly observe this core process at time t . Let T be the number of decision epochs, that is, planning horizon. If $T < \infty$, POMDP model is a finite horizon model, otherwise it is an infinite horizon POMDP.

Observations

To learn about the true value of state at time t , *observations* $\{z(t), t = 1, 2, \dots\}$ are collected.

The observation space, Z , is assumed to be finite just as the core state space S . The relationship between the core state and the observations is known to the decision maker and defined by the *information matrix* $Q = [q_{ik}]$, $i \in S, k \in Z$ where q_{ik} is the probability of observing $k \in Z$ given that the underlying state is $i \in S$.

Actions

The decision maker’s control over the system is provided by actions. At each decision epoch, t , the decision maker chooses an *action* $\{a(t), t = 0, 1, \dots\}$ from the set of available actions from the action space A where it is assumed to be finite. The state transition matrix P and the information matrix Q could be functions of the action $a(t)$. For the most general case, both matrices are assumed to be affected by the choice of action. Specifically, $P(a) = [p_{ij}(a)]$ is the probability that the system moves from core state $i \in S$ to core state $j \in S$ when action $a \in A$ is chosen. Similarly, $Q(a) = [q_{ik}(a)]$ is the probability of observing $k \in Z$ while the system’s actual state is $i \in S$ and action $a \in A$ is chosen.

Data Process and Belief States

The *data process* $\{d(t), t = 0, 1, \dots\}$ is the collection of all past and present observations and actions taken prior to time t including the initial distribution of core states, $\pi(0)$, that is, $d(t) = (\pi(0), z(t), \dots, z(1), a(t-1), \dots, a(0))$ for $t \geq 1$, where $\pi(0) = (\pi_i(0), i \in S)$ and $\pi_i(0) = \Pr\{s(0) = i\}$. The core states are only partially observable by the decision maker. Given the data process available to the decision maker, the belief state, $\pi_i(t)$, is defined as the probability of being in the core state, $i \in S$, that is, $\pi_i(t) \equiv \Pr\{s(t) =$

$i|d(t)\}$. The set of belief states, $\Pi(S)$ defined over core state space S is as follows: $\Pi(S) \equiv \left\{ \pi \in \mathbb{R}^N : \sum_{i=1}^N \pi_i = 1, \pi_i \geq 0, i = 1, \dots, N \right\}$, where N is the cardinality of core state space S .

Updating Belief States

The system transitions among belief states. An important element of this process is the timing of the state transitions. According to this timing, we present two models that differ with respect to the update function for the belief state. Although there is a slight difference in formulation, the models have been shown to be equivalent [17,18]. In the first model, MI, given the core state $i \in S$ and the chosen action $a \in A$, a transition occurs with probability $p_{ij}(a)$, and then given the transition from core state $i \in S$ to $j \in S, k \in Z$ is observed with probability q_{jk} . In the second model, MII, if the current state is $i \in S$ and action $a \in A$ is chosen, $k \in Z$ is observed with probability q_{ik} , then a transition to state $j \in S$ occurs with probability $p_{ij}(a)$. The sequence of the process in MI is action, then the state transition, and last, the observation, whereas in MII, the sequence is action first, then observation, and finally the transition of the state. Figures 1 and 2 show the schematics of the

decision process for MI and MII, respectively [7,17].

We can update our belief state for each model using Bayes' formula as follows:

$$\pi_j(t+1) = \frac{\sum_{i \in S} q_{jk}(a) p_{ij}(a) \pi_i(t)}{\sum_{i \in S} \sum_{l \in S} q_{lk}(a) p_{il}(a) \pi_i(t)} \text{ for MI} \quad (1)$$

and

$$\pi_j(t+1) = \frac{\sum_{i \in S} q_{ik}(a) p_{ij}(a) \pi_i(t)}{\sum_{i \in S} q_{ik}(a) \pi_i(t)} \text{ for MII.} \quad (2)$$

The belief state $\pi(t)$ is a sufficient statistic and contains all of the information required to update the system and for making a decision at time t [7,19].

Reward Function

To construct a POMDP model, we define an immediate reward function. The decision maker receives an immediate reward $r(i, a) \in R$ when core state is $i \in S$ and action $a \in A$ is taken. The POMDP model, $\langle S, A, Z, P, Q, R \rangle$, determines the decision rule, or policy, that yields the maximum

Figure 1. Partially observable Markov decision process for model 1, that is, assuming that the state transition occurs prior to the observation.

Figure 2. Partially observable Markov decision process for model 2, that is, assuming that the state transition occurs after the observation.

total expected reward. When determining the maximum total expected reward, a discount factor $\lambda \in [0, 1]$ can be introduced. Because the POMDP model is defined over a planning horizon, a discounted reward function is often a reasonable assumption for applications where the reward or cost accumulates over a long horizon.

Policy and Strategy

A *strategy* is defined as a sequence of policies, $\delta = \{\delta_1, \delta_2, \dots, \delta_t, \dots\}$, such that δ_t is a *policy* that determines which action in A to select at time t of the process given $d(t)$, the data available at time t . Because the process is Markovian, it is not necessary to use all of the information in the data process, $d(t)$, and the current state of the system is sufficient information for action selection. Thus, the policy can be redefined as a function of the state, which is $\delta_t : \Pi(S) \rightarrow A$. A strategy is stationary if the policy does not change from one decision epoch to another, given that the state of the process, $\pi(t)$, stays the same.

Optimal Value Function

Using the above notation, we define an optimal value function, $V_\lambda(\pi)$, to determine the policy that maximizes the total expected discounted reward. For infinite horizon problem, optimal policy can be determined by solving

the following recursion:

$$V_\lambda(\pi) = \max_{a \in A} \left\{ \sum_{i \in S} \pi_i r(i, a) + \lambda \sum_{k \in Z} V_\lambda(\pi(k, a)) \sigma(k|\pi, a) \right\} \text{ for } \pi \in \Pi(S), \quad (3)$$

where $r(i, a) \in R$ is the immediate reward function, $V_\lambda(\pi)$ is the optimal value function for belief state $\pi \in \Pi(S)$, and $\lambda \in [0, 1]$ is the discount factor [4, 12]. The probability of observing $k \in Z$, given the state $\pi(t)$ and the selected action $a \in A$, is $\sigma(k|\pi(t), a(t))$ (which is also the denominator of Equation (1)) and it is computed by

$$\begin{aligned} \Pr\{k|\pi(t), a(t)\} &\equiv \sigma(k|\pi(t), a(t)) \\ &= \sum_{j \in S} \sum_{i \in S} q_{jk} p_{ij} \pi_i(t). \end{aligned}$$

For the finite horizon problem, where $T < \infty$, the analogous recursive equation is defined as follows:

$$\begin{aligned} V_\lambda^{T+1}(\pi) &= \max_{a \in A} \left\{ \sum_{i \in S} \pi_i r^{T+1}(i, a) \right\} \\ &\text{for } \pi \in \Pi(S), \end{aligned}$$

$$V_{\lambda}^t(\pi) = \max_{a \in A} \left\{ \sum_{i \in S} \pi_i r(i, a) + \lambda \sum_{k \in Z} V_{\lambda}^{t+1}(\pi(t+1)) \sigma(k|\pi, a) \right\} \text{ for } \pi \in \Pi(S), t = 1, 2, \dots, T, \quad (4)$$

where $r^{T+1}(i, a)$ is the terminal reward received when the core state is $i \in S$ and $\lambda \in [0, 1]$ is the discount factor. For $t = 1, 2, \dots, T$, $V_{\lambda}^t(\pi)$ is the optimal value function if the system is in state $\pi \in \Pi(S)$ and there are $T - t$ periods remaining before the process ends.

Equations (3) and (4) determine the action $a^*(\pi) \in A$ that maximizes the total discounted reward in that decision epoch. The collection of these actions provides the optimal policy $\delta^* : \Pi(S) \rightarrow A$ for the process. The following simple example illustrates the application of a POMDP model to a classic machine maintenance problem.

Example

Machine maintenance is one of the earliest applications of POMDP. In this model, a machine or a system, which is observed periodically, deteriorates over time. Since deterioration involves internal components of the machine/system, the true condition of the machine/system is unknown to the decision maker. It may be possible to determine the true condition of the machine by disassembling the machine or through some other type of destructive testing, however, this procedure can be costly or unproductive. Consider a simple machine that is operating in one of the two conditions, “good” (0) or “bad” (1), $S \in \{0, 1\}$. The “bad” state corresponds to a machine that is operational but producing defective or unusable. This failure may only be identified by destructive testing; hence, the condition of the machine is partially observed. Further, observations may be based on a sample of products from a lot making the observations imperfect. There are two belief states: $\pi_t \equiv \text{Probability}\{S_t = 0\}$ and $1 - \pi_t \equiv \text{Probability}\{S_t = 1\}$. The machine starts in state 0 and enters state 1 after operating for time I , where I is a discrete random variable with a probability mass

function $f_I(i) = p_{00}(1 - p_{00})^{i-1}, i = 1, 2, \dots$. Once the machine enters 1 it stays there until exogenous action is taken. Monitoring gathers independent observations, Z_t , at time $t, t = 1, 2, \dots$, where the density of Z_t depends on the machine state with pdf, q_{0k} , if $S_t = 0$, or q_{1k} , if $S_t = 1$.

At any decision epoch, t , there are two possible actions: “do nothing” action $a_0(t)$, which allows the machine to continue to operate, and the “checking” action $a_1(t)$, which stops the machine and obtains perfect information about its condition. If the machine is found to be in state 0, it is a false alarm; if the machine is found to be in state 1, the machine is replaced and restarts in state 0. Assume that there is a fixed cost, $r(i, a)$, associated with performing action, a_1 , when the machine is in state i , where $r(1, a_1) < r(0, a_1)$. Assume that the cost per unit time for operating the machine in state i is $r(i, a_0)$, where $r(0, a_0) < r(1, a_0)$. The cost $r(1, a_0)$ serves as a penalty for false alarms while the cost $r(0, a_1)$ is the penalty per unit time associated with failing to detect.

When action $a \in \{a_0, a_1\}$ is taken, define the immediate expected cost accrued associated with each action as $r(1, a_0)(1 - \pi)$ and $r(0, a_1)\pi + r(1, a_1)(1 - \pi)$, respectively. We assume without loss of generality that $r(0, a_0) = 0$. Then, we define the minimum total expected cost with $T - t$ periods remaining, and probability π that the system is in state 0 as

$$V_{\lambda}^t(\pi) = \min_{i \in \{0, 1\}} \left\{ \begin{aligned} & r(1, a_0)(1 - \pi) + E_k[V_{\lambda}^{t+1}(\pi_{a_0}^k(t+1))] \\ & r(0, a_1)\pi + r(1, a_1)(1 - \pi) \\ & + E_k[V_{\lambda}^{t+1}(\pi_{a_1}^k(t+1))] \end{aligned} \right\},$$

where $E_k[V_{\lambda}^{t+1}(\pi(t+1)|k, a_i)] \equiv$ expectation of the minimum total cost with respect to the next observation k ; and $\pi_{a_i}^k(t+1) \equiv$ probability the state is 0 given that observation k and action a_i are selected, $i = 0, 1$.

Using Bayes’ rule, one gets

$$\pi_{a_0}^k(t+1) = \frac{(1 - p_{00})\pi q_{0k}(a_0)}{\pi q_{0k}(a_0) + (1 - \pi)q_{1k}(a_0)}$$

and because a_1 is the *renew* action, $\pi_{a_1}^k(t+1) = 1$. We assume that the value of the machine at the end of the horizon, when

9 Girshik and Rubin [23], Eckles [24], Ross [25], Smallwood and Sondik [8], Rosenfield [26], Pierskalla and Voelker [27], Wang [28,29], White [30–33], Hopp and Wu [34], Hopp and Kuo [35], Ivy and Pollock [36], Maillart [37], Kuo [38], Ghasemi <i>et al.</i> [39], Yeung <i>et al.</i> [40]	A machine or a system which is observed periodically deteriorates over time. Determination of a maintenance/replacement/inspection policy at every period that satisfies objectives of the model. Observations about machine can be used as a basis for maintenance or replacement decisions. Two types of observation can exist: outputs of the machine or outcomes of the system and inspection of the machine/system	Objective function of the model can vary. Some examples of different objective types that are applied in some of machine maintenance applications are to minimize total cost (operating cost), to maximize the production capacity, to maximize the expected length of time between replacements, and to maximize total reward	States of POMDP model are defined as the state of the machine. Maintenance models can be classified depending on the number of states. Two-state models assume the state of the machine is either “good” or “bad”. Multistate models generalize two-state models by allowing the machine to have N -level of deterioration	Since deterioration includes internal parts of the machine, the true condition of the machine is unknown to the decision maker. It is possible to disassemble the machine in order to determine the true state; however, this procedure can be costly or unproductive	Available actions for maintenance models can be any set of the following: do nothing, perform maintenance, inspect the machine, replace components, and replace the machine. (Different types of inspection can be included as well.)	Machine maintenance is one of the earliest and widely explored applications of POMDP. Not only are various types of maintenance models formulated as POMDP, for example, whether perfect information is available after inspection action, but also many researchers have developed structural properties, characterized the optimal policy, and produced conditions for control-limit type policies
Karush and Dear [41]	A subject is taught n items in the course of N trials. The model is developed for the determination of a strategy of trial-by-trial item selection	To maximize the expected terminal level of achievement of the subject	States are the knowledge of subject on any given item	It is not possible to observe knowledge fully. Responses of the subjects on the test of given items are observations for the underlying state	A reinforcement or teaching action related to item	Application of POMDP for model development in education and teaching strategies

	Kaplan [42]	Assessment of periodic financial reports of divisions in a large decentralized corporation. Reports are used as observations regarding whether or not the division is out of control	The minimum expected discounted cost given a policy is chosen.	Finite two-state system where the state is 1 if the division is operating in control or 2 if the reduction of incurred cost in the division is possible with the actions of management	Observing financial reports does not give complete information about the state of the system, that is, whether division is in control or out of control	Do nothing and investigate the division incurring a cost	Adapted a model that was developed for industrial quality control
	Pollock [43]	When a target moves between two regions in Markovian fashion, the model allocates the search effort to one region in order to locate the moving target	To minimize the expected number of observations or to maximize the probability of locating the target	Two-state model where state 1 means the target is in region 1 and state 2 means the target is in region 2. An extended model including state 3 which is the state the target moves to when it is detected	The decision maker does not exactly know the location of the moving target	To look in region 1, to look in region 2	Knowing the location of the moving target could be useful for military applications, such as locating an opponent's submarines and mobile missile platform. Technological advances like satellite images and sonar could be used for observations in the system that increases the chance of locating the target

Smallwood [44]	Optimization of the instructional decision process based on learning of students	To minimize the total expected cost of future instruction for each of the available alternative teaching strategies	State is defined as student's internal state of knowledge	Similar to Karush and Dear model, knowledge cannot be assessed entirely via student's response to the test	For an item, possible actions are to use present instructional alternative, to use "test" instructional alternative, and to terminate the instruction	Built a model to use for day-to-day operations of an educational system, developed an algorithm to solve the model, proposed an extension incorporating student's past history in the model
8 Smallwood <i>et al.</i> , [45]	Identifying patient state and physician state of information as two interrelated concepts, development of a decision-making methodology related to problems in health-care systems. Problems can be individual, such as medical diagnosis and treatment and individual facility design; or societal, such as health service programs and regional health system design	For an immunization program, the objective function can be to improve the health state of patients for a certain disease. Depending on the type of the problem, the objective function of the model differs	Patient state is defined as the internal physiological or psychological state of the patient, which is usually unobservable. Physician state of information corresponds to the physician belief regarding the patient state and depends on the physician, his prior experience, and his knowledge of the patient. These two types of states are paired for formulating the problems	The internal states of the patient are not directly observable. The physician will have data available (diagnostic tests etc.) which influence his state of information about the patient's state. Natural change in the patient's state or change in the application of the physician's action also affect the form of the state pairs.	The available actions vary in different models. In medical diagnosis and treatment problems, the actions are medical ones in response to a need. In health system design problem, the actions are policy decisions such as how much and where to spend funds	One of the earliest health-care-related paper that proposes the utilization of POMDP while defining patient health as unobserved state pairing with physician state of information. It explores a broad range of health-care system problems as promising areas to integrate twin states

	White [46]	Determination of the optimal sequence of questions, or a questionnaire in order to identify the state of the system while allowing for answers that are not necessarily truth	To minimize the expected terminal cost	Any system with an underlying process which can be identified with a set of diagnostic questions. If the system has finite number of states and it doesn't change state during questions, then the given model can be used to diagnose the state optimally.	As a prior assumption, the state of the system is unobservable and the questionnaire is used to diagnose the underlying state.	The sequence of questions to be asked.	A POMDP application on questionnaire design. Model is slightly different version of the POMDP where transition of the states during questionnaire is not allowed. Sufficient conditions for an optimal questionnaire to obtain a lower limit are also determined.
6	Segall [47]	While only one copy of a file is allowed to exist in a computer network, the goal is to determine the optimal policies for dynamic allocation of files in the computer network that works under time-varying operating conditions	To minimize total expected cost where the cost function includes storage cost of a file in a computer and transmission cost of a file from one computer to another in the network	Demand rate of files is assumed to be the state of the system	Two models are developed in the article. One assumes a known demand rate, whereas the second model is constructed with unknown demand rates since it is usually difficult to know demand rates perfectly as a function of time	While the file is stored in a computer i at time t , the available actions are to leave the file in computer i , to transfer the file to computer j which requests that file at time t	A POMDP application on network design

Hughes [48]	Construction of a general decision model appropriate for the determination of the optimal timing of internal audits. Audit is one of the actions that provides information about the internal control process of a firm	The minimum total expected discounted costs	States of the model are the effectiveness of internal control process of the firm	Auditors cannot observe the state of internal control process. However, they have a belief about the state	Do nothing, audit, and restore. It is also mentioned that as long as action space is finite, any control action related to internal control process can be added as action into the model	Model is similar (or adapted from) the Ross model of quality control under Markovian deterioration
Lane [49]	Determining dynamic decision policies for the intraseasonal decisions of individual fishing vessel operators. When and where to fish throughout the season with the highest return on seasonal income for independent fishermen will be decided according to the optimal policy.	To maximize net operating income	The state space is assumed to be fish abundance; in a particular model, it is salmon abundance.	The fish stock abundance is not directly observable by the decision maker. However, the average fish catch by individual fishermen provides an imperfect measure of stock abundance.	The action space is assumed to be interzonal movements. In other words, action in any period describes the movement from current zone to another in the fishery, including no fishing option.	A real-life application of POMDP that may be used as a decision tool in the regulation of fisheries.

Koenig and Simmons [50,51]	An autonomous robot requires having a reliable navigation system to complete its function. Authors developed a navigation architecture on the basis of POMDP that robustly tracks a robot's location indoors and directs its goal-oriented actions	To minimize the expected total cost while in every decision epoch an immediate cost is measured as the expected travel times needed to complete the actions	The pose of the robot is the state of the model. The orientation and the position of the robot are defined as the pose. The states are classified according to environmental parameters such as doors and walls	Uncertainty in actuator, sensor noise, incomplete knowledge of the environment, and uncertainty in the initial pose of the robot make the state unobservable. Thus, the robot never actually knows its exact location but has some belief regarding its location from sensor data	The actions are “the motion reports” for pose estimation and “the directives” for policy generation	POMDP application on robot navigation. It is proved that this architecture leads robust indoor navigation for an actual robot
Crites and Barto [52]	Elevator dispatching problem explores good policies for the control of elevator systems while improving performance. The article provides an application of reinforcement learning to the elevator dispatching problem which is known to be DP intractable	Possible objectives are minimizing the average wait time or the average system time, minimizing the percentage of passengers that are waiting longer than a dissatisfaction threshold time, and minimizing sum of squared wait times	Positions and directions of the elevator cars as well as the desired destinations of the passengers waiting in each floor are established as the state of the model	Because the system has varying passenger arrival rates and the call buttons on every floor, it does not provide enough information about the number of the passengers waiting and their desired destinations, and the state of the system is unobservable	Action space consists of some possible primitive actions for each elevator car: if it is stopped at a floor, it must either “move up” or “move down”, and if it is in motion between floors, it must either “stop at the next floor” or “continue past the next stop”	A real-life application of reinforcement learning (RL) for elevator dispatching. Since an optimal policy is unknown, the performance of RL-based algorithm is compared to some other elevator dispatching heuristics and it is shown to perform well in comparison heuristics. This demonstrates utility of RL in large-scale dynamic optimization problems

Darrell and Pentland [53]	An active gesture recognition (AGR) is designed based on POMDP in which an active camera is guided to foveate (focus on) for discriminating a certain gesture of the target.	To maximize the expected future reward where reward function consists of a unit positive reward when system detects the target and a unit negative reward when system fails to recognize target.	The states of the model are the states of the targeted person such as the targets' pose, facial expression, and hand configurations.	Since a foveated image sensor can only focus on a single body part not the whole body, the target's gesture cannot be recognized fully resulting with partial observability of the surroundings.	The set of actions are four foveation commands: look-body, look-head, look-right-hand, and look-left-hand. Each action lets the active camera to track a certain body part.	A POMDP application on machine vision. Q-learning algorithm adapted for gesture recognition of a foveated vision system.
Hu <i>et al.</i> [54]	Efficient dosage policies in drug therapy should maintain drug concentration at a target. Presentation of an infinite horizon POMDP model for a drug infusion problem which determines how to choose the infusion rate and how to administer the most effective dosage pattern	To minimize the total expected discounted cost where the cost function depends on the dosage and penalizes deviations from the target concentration	State space corresponds to the volume, clearance, and current drug concentration	Drug concentration is measured through observations that are prone to errors. Because exact drug concentration could not be observed, the model is partially observable	Action space contains nonnegative infusion rates	A POMDP model is developed to provide policies for adaptive control of drug concentration. However, the model is intractable and authors introduce approximation techniques to generate suboptimal candidate policies

Hauskrecht [55], Hauskrecht and Fraser [56,57]	Development of a POMDP framework for medical therapy planning for patients with ischemic heart disease (IHD)	To minimize the expected cumulative cost of the treatment, where the cost is defined in terms of dead–alive trade-off, quality of life, invasiveness of procedures and their economic cost	The state of the model is defined as the state of the patient or disease. If the patient’s status is alive, the state is described with a set of variables and their values. Some examples of these variables are coronary artery disease (mild, severe etc.), chest pain (no pain, mild etc.), stress test result (positive, negative), ischemia level (no ischemia, mild, severe), and so on	The diagnosis of a disease and its treatment are often practised without knowing the underlying patient state. The underlying disease state is observed indirectly using incomplete or imperfect observations	Actions are categorized as treatment and investigative actions. Treatment actions are “wait”, “medication”, “angioplasty,” and “coronary artery bypass graft surgery,” and in general, these actions result in an active change in the patient state to a more appropriate one. Investigative actions are “stress test” and “coronary angiogram,” and they may not only reveal something about the hidden disease state but also yield a change in the state	POMDP is suggested as an elegant framework for modeling medical therapy since it captures both uncertainty related to the control process (outcomes of treatment and diagnostic actions are not predictable) and partial observability of the disease process. The application of POMDP to a medical therapy planning problem is demonstrated with the IHD model

Murphy [58]	When an autonomous robot navigates in a dynamic environment, it must handle changes in the environment, such as closing doors and moving objects. A model for the map learning of a robot in such an environment is presented	A simple policy is developed for the model instead of solving the model for optimal policy. The policy is to visit the nearest uncertain cell. After successfully learning the map of an environment, the robot keeps running to update its map	The location of the robot corresponds to the state of the model	Similar to the Koenig and Simmons model, the robot's understanding of its location is incomplete and the sensors provide observations about its possible location	The actions are moving one step ahead in each of the four compass directions	Incorporation of dynamic environment into the POMDP models of robot navigation
Roy <i>et al.</i> [59]	A POMDP dialog manager is generated for recovering from noisy or ambiguous utterances in speech recognition systems	To maximize the reward obtained for fulfilling a user's request. Choosing the correct action leads to a positive reward,; on the other hand, incorrect actions are penalized by an equivalent negative amount	The states are the intentions of the user with respect to dialog task. A nursing home assistant robot is used to conduct experiments. In this example, the states of the model are determined as the tasks that are relevant for an assisted living in nursing home such as "bring medication" and "want TV information"	Human speech can be noisy and ambiguous. The dialog manager does not have direct knowledge regarding what the user wants, that is, the state of the system. It uses noisy speech utterances from the user to understand the task	Robot's responses to the dialog are the actions of the model. In the nursing home robot example, these actions are determined as follows: 10 actions correspond to the different abilities of the robot, such as going to kitchen, or providing the time, the remaining 10 actions are clarification and confirmation actions such as reconfirming the desired TV channel	A POMDP-based spoken dialog is developed and tested to handle noisy speeches. It is shown that under the same conditions, the POMDP dialog manager outperforms MDP dialog manager

Regan <i>et al.</i> [60]	A POMDP model (advisor-POMDP) that examines trust through reputation in electronic markets is proposed. This decision-theoretic framework describes the problem with the help of buying and selling agents. Buyers make purchases depending on advisors' information regarding seller's reputation	To maximize the expected reward, where the reward function has two components: a cost associated with asking an advisor about a selling agent and a reward which can be positive or negative depending on satisfaction from the purchase	A state of the advisor-POMDP consists of a vector of real values between 0 and 1 representing the reputation of each seller and a scalar value representing satisfaction resulting from a purchase	States of the model include the reputation of each selling agent. However, the buyer will have limited information about each seller's reputation since it only has some knowledge about a seller's past interactions	Actions that are designed for buying agents are asking an advisor for information about a selling agent or buying from a selling agent	The advisor-POMDP models the uncertainty inherent in social reputation systems for electronic markets. The framework allows buyers to make informed purchases using the information about a seller's reputation
Boger <i>et al.</i> [61]	Task assistance for people with dementia provides guidance when problems arise with completing activities of daily living (ADL) such as handwashing and dressing. MDP and POMDP models are developed for a specific ADL, that is, handwashing, and it is stated that the model is generalizable for almost any ADL assistance	To maximize the expected discounted sum of rewards. The reward function is designed to cover conflicting objectives such as maximizing the odds of task completion, minimizing caregiver intervention, and minimizing user frustration	Four classes of variables construct the state space of the model: those that capture the state of environment (hand location, water on/off), those that summarize ADL plan steps completed thus far (most recent step, maximum plan steps completed, current step that is repeated, etc.), those summarizing system behavior	Sensor noise causes environment variables and task steps to be estimated imperfectly	The model has 20 actions. Eighteen actions comprise prompts for six different plan tasks (water on/off, use soap, wet hands, rinse hands, dry hands) at three levels of specificity (general, moderate, and specific). The other two actions are "null" action and "call caregiver"	POMDP is offered as an ideal model for the decision process for ADL assistance since it captures stochasticity, noise, conflicting objectives, and the ability to customize behavior to specific individuals. The POMDP model for handwashing is solved approximately to develop optimal policies for ADL prompting

(continued overleaf)

Table 2. (Continued)

References	Short Summary of Problem	Objective Function	Definition of States	Why It Is Partially Observable	Action Space	Comments
		(number of prompts issued for the current plan step, type of last prompt, etc.), and those reflecting certain hidden aspects of the user's personality or mental state (e.g., general responsiveness, low or high)				
16 Williams and Young [62]	POMDP is proposed as a single framework (SDS-POMDP) which can unify and extend existing methods for improving the robustness of spoken dialog systems	The reward function in the framework is not specified explicitly, since it depends on design objectives of the target system. Some objective function examples given are maximizing the chance of successful closure and minimizing the number of turns required	A factored state-space representation is presented where the unobserved state of the SDS-POMDP can be factored into three distinct components: the user's goal, the user's action, and the dialog history	One reason why spoken dialog systems are challenging is that the estimate of a user's action is noisy, that is, the user's goal derived from its speech contains recognition errors. As a result, the state of the model is not directly observable and can never be known with certainty	The machine's actions are cast as the action space in the factored model	The SDS-POMDP framework is presented as a well-suited model in order to cope with the uncertainty present in spoken dialog systems and ambiguity of speech patterns. Practical advantages of utilizing the framework are also demonstrated

Maillart <i>et al.</i> [63]	Development of a partially observed Markov chain model of breast cancer progression in order to assess screening policies. The aim is to investigate the relative value and frequency of mammography screening for premenopausal women versus postmenopausal women	Although the model is not solved to optimality, the value of a screening policy is measured by lifetime mortality risk, that is, how likely a patient is to die from breast cancer over her lifetime under a certain screening policy	The states of the model are no breast cancer (state 0), early breast cancer (state 1), later/advanced breast cancer (state 2), breast-cancer-induced death (state 3) and non-breast-cancer-induced death (state 4)	Because transition between states 0, 1, and 2 is not visible without screening or diagnostic tests and mammograms may produce false positive and false negative results, the disease state is partially observable	Different screening policies are the actions of the model since they affect the underlying core state	Natural history of breast cancer is formulated as a partially observed Markov chain to generate a frontier of efficient screening policies by evaluating them according to lifetime mortality risk and expected mammogram count.
--------------------------------	--	---	--	--	---	--

there are no observations remaining and the process terminates, is zero regardless of the state, that is, $V_{\lambda}^0(\pi) = 0 \forall \pi$. $V_{\lambda}^T(\pi)$ is the optimal or minimal cost for a T -period finite horizon. Shiryaev proved that the fixed probability threshold rule for this type of two-state model with geometric failure times minimizes the average cost per unit time. This rule states that if π , the posterior probability of the system operating in the “good” condition, is less than or equal to some threshold value, then a “checking” action should be taken. Refer to Ivy and Nembhard [20] for sample solutions for the two-state machine-problem probability thresholds. Structural results such as this one can provide information about the form of the optimal policy and typically accelerate the solution procedure. However, owing to the uncertainty of the initial state and imperfect information regarding the underlying state, structural properties that are often exploited in MDPs cannot be determined for POMDPs [17]. In the following section, we present several applications of POMDPs.

APPLICATIONS OF POMDP

A POMDP is recognized as an appropriate technique for modeling problems with incomplete information and stochastic nature. While numerous articles provide theoretical contributions for the analysis and characterization of POMDPs, there is significant research that applies POMDPs to practical problems. Several problems in a wide variety of areas with these features can be formulated as POMDPs. Monahan and Cassandra’s surveys provide summaries of the literature for several of these applications [17,21]. In addition, the recent tutorial by Littman presents more examples and suggests that the POMDP may be an effective tool for behavioral science problems [22]. Table 2 presents a summary of several significant application domains for POMDPs.

SUMMARY AND CONCLUSION

In this article partially observable Markov decision processes are introduced and

reviewed and the relationship between POMDPs and MDPs is discussed. The general model formulation and the decision process of POMDP models are explained. Applications of POMDPs in the literature are presented chronologically. The states, objective function, and action sets of the POMDP models for these applications are discussed with a brief explanation of the model topic. The reasons for the partial observability of the states are explained for each application.

PASTA AND RELATED RESULTS

MUHAMMAD EL-TAHA
Department of Mathematics and
Statistics, University of Southern
Maine, Portland, Maine

Poisson arrivals see time averages (*PASTA*) is one of the fundamental properties of queueing and related stochastic systems. *PASTA* and its generalization arrivals see time averages (*ASTA*) play an important role in the analysis and understanding of stochastic systems. Its usefulness covers a wide range of applications.

Consider a queueing process with an associated arrival process satisfying a lack-of-anticipation assumption (*LAA*), which says that future arrivals occur independently of the present and past behavior of the queueing process. If the arrival process is Poisson, then *PASTA* says that an arriving customer sees the same as an independent outside observer (i.e., customer averages are the same as time averages). More generally, consider a random process X (the state of the system) that evolves in continuous time such that its states may be sampled (observed) at a sequence of discrete events (an imbedded point process N). For a given set of states, form the time-average and the event-average frequencies of the process. Then the question of whether or not *arrivals see time averages* is concerned with finding sufficient and/or necessary conditions for the equality of event and time averages.

This article is organized as follows: in the section titled “Setting and Problem Definition,” we provide the problem setting and definitions. We also give Wolff’s *PASTA* under *LAA* and give examples of where *PASTA* holds, and where it fails. In the section titled “Sample-Path Framework,” we discuss *PASTA/ASTA* in a sample-path framework. The results pertaining to conditional *ASTA*, and reversed *ASTA* have been included. Several simple examples are provided. In the section titled “Stochastic

Framework,” *ASTA* results are given in a stochastic framework. We use the expectation framework provided by Melamed and Whitt [1], where we give the lack-of-bias-assumption (*LBA*) and discuss its connection to a similar condition given in the sample-path framework. Finally, in the section titled “Remarks and References,” we provide a literature review emphasizing *PASTA* type results and applications that are not covered in this article.

SETTING AND PROBLEM DEFINITION

Let $(\Omega, \mathcal{F}, \mathcal{P})$ be the common probability space over which all stochastic processes will be defined. Let $X \equiv \{X(t), t \geq 0\}$ be a stochastic process taking values in a complete separable metric space, S , with the associated σ -algebra, $\mathcal{G}$, generated by the open sets. Let $N \equiv \{N(t), t \geq 0\}$ be a simple counting process, which is nonnull and nonexplosive, that is, $0 < E[N(t)] < \infty, t > 0$. The jump times of N form a stochastic sequence $T \equiv \{T_n, n \geq 0\}$, where $T_n = \inf\{t > 0, N(t) \geq n\}$ for $n \geq 1$, and $T_0 = 0$ by convention. The process X is referred to as the *state* process and represents the stochastic evolution of the system of interest. Let the sample paths of X be right-continuous with left-hand limits. The counting process N is referred to as the *arrival* process, and its jump times constitute the imbedded times of the state process, that is, the imbedded state process is a stochastic sequence $X^N \equiv \{X(T_n-), n \geq 0\}$. Define the following limits when they exist.

$$V(t) = t^{-1} \int_0^t f(X(s)) ds \quad \text{and} \quad (1)$$

$$W(n) = n^{-1} \sum_{k=1}^n f(X(T_k-)), \quad (2)$$

where f is any real-valued bounded function. Here, $V(t)$ is a time average while $W(n)$ is an imbedded event (arrival) average.

In many applications, the points of N will be a subset of the set of points where X

changes state. For example, X can be the queue length process in a $G/G/1$ queue and N , the points at which X makes a transition from state i to state $i + 1$ for some $i \geq 0$ (i.e., an arrival occurs). In this example, our definition of N ensures that an arrival does not see itself. In such applications, $\{N(s) : 0 \leq s \leq t\}$ is completely determined by $\{X(s) : 0 \leq s \leq t\}$. See Refs 2–5 for applications to Markov processes that exploit this property. Our more general framework is consistent with that of Refs 1, 6–10 in the sense that it is not necessary that all, or any of the points of N coincide with the changes of state of X .

As an extreme case, N could represent the time points of observations that occur independently of the evolution of X . As an application of this situation, suppose that we are interested in estimating the probability that a (strictly) stationary stochastic process X belongs to a set of states B . By the Ergodic Theorem, this probability is (a.s.) equal to the asymptotic time-average fraction of time that the process spends in B . The results in this article confirm that we can obtain an estimate of these probabilities by sampling the process over a sequence of discrete-time points (i.e., there is no need to continuously observe the process over time) provided that the sequence of sampling instants and the original process satisfy the *LAA* assumption. One way to guarantee that *LAA* is satisfied is to ensure that the time between sampling instants are *iid*, exponentially distributed, and independent of the state of the original process. For instance, consider a communication link between two subnets. It is often necessary to collect data to measure the performance of the link (utilization, job processing times, delay, and so on). Continuous monitoring of the link can degrade the performance due to unacceptable overhead. If the link is observed (sampled) at predetermined discrete-time points (so that *LAA* holds), we can ensure that the collected event-average statistics provide good approximations of the statistics of interest without seriously degrading system performance.

We shall need the following *LAA* introduced by Wolff [6].

Assumption [LAA]. For all $t \geq 0$, $\{N(t + h) - N(t); h \geq 0\}$ is independent of $\{X(\tau); 0 \leq \tau \leq t\}$.

The *LAA* assumption implies that the number of points from N after time t is independent of the past behavior of the process X . Melamed and Whitt [8] and Stidham and El-Taha [11] show that the whole past may be replaced by the present when joint stationarity of X and N is assumed. We state a slight variation of *PASTA* as given by Wolff [6].

Theorem 1. *Under the assumptions that N is a Poisson process and *LAA* holds, $V(t) \rightarrow V(\infty)$ w.p.1 if and only if $W(n) \rightarrow W(\infty)$ w.p.1 in which case*

$$W(\infty) = V(\infty) \text{ w.p.1.}$$

Special Cases

(i) Let B be any subset of the state space of X . Now let f be an indicator function such that $f(\cdot) = \mathbf{1}\{X(\cdot) \in B\}$. Then we obtain Wolff's *PASTA*, which says that the probability that an arrival sees X in set B is the same as the time-average probability that X is in set B ; that is, the probability that an arrival sees $X \in B$ is the same as the probability a random observer sees $X \in B$. More precisely,

$$\begin{aligned} \lim_{n \rightarrow \infty} n^{-1} \sum_{k=1}^n \mathbf{1}\{X(T_k-) \in B\} \\ = \lim_{t \rightarrow \infty} t^{-1} \int_0^t \mathbf{1}\{X(s) \in B\} ds \text{ w.p.1. } (3) \end{aligned}$$

(ii) Consider an $M/GI/1$ queue where $X(t)$ is the number of customers in the system at time t , and service times are *iid* and independent of the arrival process. Let f be the identity function. Clearly, the conditions of *PASTA* hold. Then the *PASTA* property says that the long run time-average number of customers in the system $L = \lim_{t \rightarrow \infty} t^{-1} \int_0^t X(s) ds$ is equal to the long run average number of customers in the system as seen by arrivals $L_A = \lim_{n \rightarrow \infty} n^{-1} \sum_{k=1}^n X(T_k-)$. Here, $\{T_k, k \geq 1\}$ represent arrival instants. Now if T_k represents departure instants, then *PASTA* says L is equal to the mean

number of customers in the system as left behind by departing customers.

(iii) Let $X(t)$ represent the work in a single server queueing system at time t , and f be the identity function. Then $W(\infty)$ is the average work in the system at arrival instants (average delay per customer) and $V(\infty)$ is the average work in the system as seen by a random observer (virtual work in the system). PASTA ensures the equality of the time and arrival averages, that is, $W(\infty) = V(\infty)$ w.p.1.

(iv) Here, we give an example where PASTA does not hold. Consider a $GI/GI/1$ queueing model where time between arrivals are iid and uniform (1.5,2.5), and service times are deterministic and equal to 1. Then $\rho = \lambda/\mu = 0.5$, so $p(0) = p(1) = 0.5$. However, the arrival probabilities are $\pi^-(0) = 1$ and $\pi^-(n) = 0, n \geq 1$.

SAMPLE-PATH FRAMEWORK

In this section, we present ASTA in a sample-path framework. Included are the results pertaining to conditional ASTA, and reversed ASTA. Several simple examples are provided. We shall begin with the following preliminary results.

Background on Point Processes; $Y = \lambda X$

Let $\{T_k, k \geq 1\}$ be a deterministic sequence of time points, with $0 \leq T_k \leq T_{k+1} < \infty, T_0 = 0$, and $k \geq 1$. Define $N(t) := \max\{k \geq 1 : T_k \leq t\}$, $t \geq 0$. We interpret T_k as the time point at which the k th of a sequence of events occurs, such as the k th arrival to a queue, and $N(t)$ as the number of events in $[0, t]$. Note that our definition allows more than one event to occur at the same time point (e.g., batch arrivals). That is, the point process $N = \{N(t), t \geq 0\}$ need not be simple. We assume that $T_k \rightarrow \infty$ as $k \rightarrow \infty$, so that there are only a finite number of events in any finite time interval ($N(t) < \infty$ for all $t \geq 0$). Note that $N(t) \rightarrow \infty$ as $t \rightarrow \infty$, since $T_k < \infty$ for all $k \geq 1$.

First, we state the following elementary lemma, which is a sample-path analog of the elementary renewal theorem. (For a proof, see Refs 12, 13.)

Lemma 1. *For any $0 \leq \lambda \leq \infty$, the following are equivalent:*

1. $N(t)/t \rightarrow \lambda$, as $t \rightarrow \infty$;
2. $T_n/n \rightarrow \lambda^{-1}$, as $n \rightarrow \infty$.

The following lemma is a sample-path analog of the renewal-reward theorem ($Y = \lambda X$).

Lemma 2. *Suppose $t^{-1}N(t) \rightarrow \lambda$, $0 \leq \lambda \leq \infty$, as $t \rightarrow \infty$. Let $\{X_k, k \geq 1\}$ be a deterministic sequence of nonnegative real numbers and define*

$$Y(t) := \sum_{k=1}^{N(t)} X_k, \quad t \geq 0. \quad (4)$$

Then

1. *if $n^{-1} \sum_{k=1}^n X_k \rightarrow X$, $0 \leq X \leq \infty$, as $n \rightarrow \infty$, then $t^{-1}Y(t) \rightarrow Y = \lambda X$ as $t \rightarrow \infty$, provided that λX is well defined;*
2. *if $t^{-1}Y(t) \rightarrow Y$, $0 \leq Y \leq \infty$, as $t \rightarrow \infty$, then $n^{-1} \sum_{k=1}^n X_k \rightarrow X = \lambda^{-1}Y$ as $n \rightarrow \infty$, provided that $\lambda^{-1}Y$ is well defined.*

Remark. Lemmas 1 and 2 pertain to deterministic processes, or, equivalently, to individual sample paths of stochastic processes. Thus, they do not require explicit stochastic assumptions, only the existence of certain limiting averages on the sample path in question. One can apply these results to stochastic models in which the stochastic assumptions imply (via an ergodic theorem or law of large numbers) that the sample-path averages in question exist almost surely. For example, suppose that $\{(T_n - T_{n-1}, X_n)\}$ is an ergodic, strictly stationary sequence and that $\{Y(t), t \geq 0\}$ is defined in terms of $\{X_k, k \geq 1\}$ by Equation (4). Then the ergodic theorem and Lemma 2 imply that $n^{-1}T_n \rightarrow E[T_1] = \lambda^{-1}$ and $n^{-1} \sum_{k=1}^n X_k \rightarrow E[X_1]$ a.s. as $n \rightarrow \infty$, and that $t^{-1}Y(t) \rightarrow Y = E[X_1]/E[T_1]$ a.s. as $t \rightarrow \infty$. Other variants of Lemma 2 are given by El-Taha and Stidham [7,14]. See the sections on “Point Processes and Renewal” in this encyclopedia and the article **Regenerative Processes** for further information on these topics.

Relations between Frequencies for a Process with an Imbedded Point Process

In this section, we use $Y = \lambda X$ to give simple derivations of relations between time-average and point-average frequency distributions for processes with imbedded point process. Specifically, we will give the covariance formula that leads to conditions for ASTA.

Let $X = \{X(t), t \geq 0\}$ be a deterministic continuous-time process with state space S . We assume that S is a Polish (complete separable metric) space, with the Borel σ -field $\mathcal{B}(S)$, and that X is right-continuous with left-hand limits. Let $\{T_n, n \geq 1\}$ be an associated deterministic point process with counting process $N = \{N(t), t \geq 0\}$ satisfying the conditions of the section titled “Background on Point Processes; $Y = \lambda X$.” (Recall that these conditions do not include a requirement that N be simple.)

The process N may (but does not necessarily) count transition instants of process X ; for example, level crossings or points where upward or downward jumps (e.g., arrivals or departures in a queueing system) occur. In general, transition instants can be points of continuity as well as points of discontinuity of process X .

For an arbitrary set of states $B \in \mathcal{B}(S)$, define the following limits, when they exist:

$$\lambda := \lim_{t \rightarrow \infty} \frac{N(t)}{t} = \lim_{n \rightarrow \infty} \frac{n}{T_n}, \quad (5)$$

$$p(B) := \lim_{t \rightarrow \infty} t^{-1} \int_0^t \mathbf{1}\{X(s) \in B\} ds, \quad (6)$$

$$q(B) := \lim_{t \rightarrow \infty} \frac{\int_0^t \mathbf{1}\{X(s-) \in B\} dN(s)}{\int_0^t \mathbf{1}\{X(s) \in B\} ds}, \quad (7)$$

$$\pi^-(B) := \lim_{n \rightarrow \infty} n^{-1} \sum_{k=1}^n \mathbf{1}\{X(T_k-) \in B\}. \quad (8)$$

That is, λ is the rate of the point process N , $\{p(B), B \in \mathcal{B}(S)\}$ is the time-average frequency distribution of the process X , $q(B)$ is the conditional rate of N while $X(t-)$ is in B , and $\{\pi^-(B), B \in \mathcal{B}(S)\}$ is the point-average frequency distribution of $\{X(t-), t \geq 0\}$. In the “classical” application to queueing systems,

N is the arrival process and $\pi^-(B)$ is the frequency with which arrivals “see” the system in the set of states B . (Recall that $X(t)$ is right-continuous with left limits, so that $X(T_k-)$ is the state of the system just before the k th “arrival.”)

In what follows, we shall make frequent use of the identity

$$\int_0^t \mathbf{1}\{X(s-) \in B\} dN(s) = \sum_{k=1}^{N(t)} \mathbf{1}\{X(T_k-) \in B\}. \quad (9)$$

The following theorem gives a relation between the time-average frequency of the set B and the frequency of B “as seen by an arrival.”

Theorem 2. *Let $B \in \mathcal{B}(S)$ and assume that the limits λ and $q(B)$ exist, $0 \leq \lambda < \infty$, $0 \leq q(B) < \infty$. Then $p(B)$ exists if and only if $\pi^-(B)$ exists, in which case*

$$p(B)q(B) = \lambda\pi^-(B). \quad (10)$$

Proof. Let $Y(t) = \int_0^t \mathbf{1}\{X(s-) \in B\} dN(s)$, so that $Y(t)$ is the number of points that occur in $[0, t]$ while $X(s-) \in B$, $t \geq 0$. Let $X_k = \mathbf{1}\{X(T_k-) \in B\}$, $k \geq 1$ and apply Lemma 2, using Equation (9) and the fact that $\lim_{t \rightarrow \infty} t^{-1}Y(t) = p(B)q(B)$, when the limits exist.

Remark. Theorem 2 plays a role similar to the Palm transformation formula in the stochastic theory of marked point processes and processes related to point processes (7, Appendix A), [15–18] (see also the section on “Point Processes” in this encyclopedia). Some authors call Theorem 2 the *covariance formula* [1, 14].

Reversed Processes. Now we give sample-path versions of these relations for reversed processes, again using the same framework as for ASTA. We begin by defining

the following limits when they exist, for $B \in \mathcal{B}(S)$:

$$q'(B) := \lim_{t \rightarrow \infty} \frac{\int_0^t \mathbf{1}\{X(s) \in B\} dN(s)}{\int_0^t \mathbf{1}\{X(s) \in B\} ds}, \quad (11)$$

$$\pi^+(B) := \lim_{n \rightarrow \infty} n^{-1} \sum_{k=1}^n \mathbf{1}\{X(T_k) \in B\}. \quad (12)$$

That is, $q'(B)$ is the *conditional rate* of N while the reversed version of process X is in B , and $\{\pi^+(B), B \in \mathcal{B}(S)\}$ is the *point-average frequency distribution* of $X = \{X(t+), t \geq 0\}$. (Recall that X is right-continuous.) Informally, we refer to $\{\pi^+(B), B \in \mathcal{B}(S)\}$ as the frequency distribution for X “just after” a point from N has occurred. Equivalently, it is the frequency distribution of the reversed version of X “just before” a point from N occurs. In applications to queueing systems, N is often the process that counts departures and hence $\{\pi^+(B), B \in \mathcal{B}(S)\}$ is the frequency distribution of the state of the system “left behind” by a departure.

By a proof exactly parallel to that used to prove Theorem 2 one can derive the following relation between $p(B)$ and $\pi^+(B)$, assuming the relevant limits are well defined:

$$p(B)q'(B) = \lambda\pi^+(B). \quad (13)$$

Equation (13) will be used to give necessary and sufficient conditions for *ASTA*-type results for reversed processes.

Characterization of *ASTA* and Related Properties

Theorem 2 yields necessary and sufficient conditions for the *ASTA* property, as shown in the following theorem. (To simplify the presentation of our results throughout this section, we shall assume that all relevant limits are well defined and that $\{p(B), B \in \mathcal{B}(S)\}$ and $\{\pi^-(B), B \in \mathcal{B}(S)\}$ are proper frequency distributions.)

Theorem 3 [Conditions for *ASTA*]. For all $B \in \mathcal{B}(S)$,

$$p(B) = \pi^-(B) \Leftrightarrow q(B) = \lambda.$$

Moreover, the following are equivalent:

1. $q(B)$ is independent of B , $B \in \mathcal{B}(S)$;
2. $q(B) = \lambda$, for all $B \in \mathcal{B}(S)$;
3. the frequency distributions $\{p(B), B \in \mathcal{B}(S)\}$ and $\{\pi^-(B), B \in \mathcal{B}(S)\}$ coincide.

Proof. The proof follows immediately from Theorem 2.

Remark. This theorem can be used as the starting point for a proof of *PASTA*. Most proofs of *PASTA* in the literature [6] contain a step in which it is shown that Poisson arrivals together with a *LAA* (roughly speaking, the future of N does not depend on the past or present of X) imply that $q(B) = \lambda$, for all $B \in \mathcal{B}(S)$, or the probabilistic equivalent of this statement. El-Taha and Stidham [19,20] use martingale and weak-convergence theory to prove stronger results under the assumptions of Wolff [6]. In particular, it is shown that the Poisson point process N , restricted to times t when $X(t) \in B$, is a probabilistic replica of the original point process; that is, it is Poisson with the same rate λ .

Conditional *ASTA*. Now we provide a sample-path proof of conditional *ASTA* in the same framework as used above for *ASTA*. Let $A \in \mathcal{B}(S)$, $B \in \mathcal{B}(S)$. Then by Theorem 2,

$$p(A \cap B)q(A \cap B) = \lambda\pi^-(A \cap B). \quad (14)$$

Define the following limits, assuming they exist:

$$p(A | B) := \lim_{t \rightarrow \infty} \frac{\int_0^t \mathbf{1}\{X(s) \in A \cap B\} ds}{\int_0^t \mathbf{1}\{X(s) \in B\} ds}, \quad (15)$$

$$\pi^-(A | B) := \lim_{n \rightarrow \infty} \frac{\sum_{k=1}^n \mathbf{1}\{X(T_k-) \in A \cap B\}}{\sum_{k=1}^n \mathbf{1}\{X(T_k-) \in B\}}. \quad (16)$$

Then it follows from Equations (6) and (15) that

$$p(A | B) = \frac{p(A \cap B)}{p(B)}, \quad (17)$$

and from Equations (8) and (16) that

$$\pi^-(A | B) = \frac{\pi^-(A \cap B)}{\pi^-(B)}, \quad (18)$$

Clearly then $p(A | B)$ and $\pi^-(A | B)$ are sample-path versions of the conditional probabilities of A given B at an arbitrary time point and at a point of the imbedded point process, respectively. Now, multiplying both sides of Equation (17) by $q(A \cap B)$ and dividing both sides of Equation (17) by $q(B)$,

$$\begin{aligned} \frac{p(A | B)q(A \cap B)}{q(B)} &= \frac{p(A \cap B)q(A \cap B)}{p(B)q(B)} \\ &= \frac{\lambda \pi^-(A \cap B)}{\lambda \pi^-(B)} \\ &= \pi^-(A | B), \end{aligned}$$

from which we obtain the following sample-path version of the *covariance formula* for conditional probabilities:

$$p(A | B)q(A \cap B) = \pi^-(A | B)q(B). \quad (19)$$

As a corollary of this result we obtain the following conditions for conditional ASTA:

Theorem 4 [Conditional ASTA]. *Let $B \in \mathcal{B}(S)$ be given. For all $A \in \mathcal{B}(S)$,*

$$p(A | B) = \pi^-(A | B) \Leftrightarrow q(A \cap B) = q(B).$$

Moreover, the following are equivalent:

1. $q(A \cap B)$ is independent of A , $A \in \mathcal{B}(S)$;
2. $q(A \cap B) = q(B)$, for all $B \in \mathcal{B}(S)$;
3. the conditional frequency distributions $\{p(A | B), A \in \mathcal{B}(S)\}$, and $\{\pi^-(A | B), A \in \mathcal{B}(S)\}$ coincide.

Remark. Intuitively, these results are just Theorems 2 and 3 restricted to B -time, that is, to time points when the process $\{X(t), t \geq 0\}$ is in the fixed set B . One can use this intuition

to construct alternate proofs of Equation (19) and Theorem 4 based on a change-of-time argument (Section 3.5, of Ref. 19), where the concept of B -time is used for a different but related purpose).

Remark. In Refs 1, 21, and 22, conditional ASTA is studied in the special case of a two-dimensional process, $X = (X_1, X_2)$, with state space $S = S_1 \times S_2$ and σ -field $\mathcal{B}(S) = \mathcal{B}(S_1) \otimes \mathcal{B}(S_2)$. In this context, one is interested in the limiting time-average and point-average conditional frequencies with which $X_1(t) \in A_1$, given $X_2(t) \in A_2$, for $A_1 \in \mathcal{B}(S_1)$, $A_2 \in \mathcal{B}(S_2)$. By setting $A = A_1 \times S_2$ and $B = S_1 \times A_2$, in Equation (19) and Theorem 4, one obtains the results presented in Refs 1, 21, and 22.

Reversed Processes and DSTA. Now we give sample-path versions of ASTA-type results for reversed processes, using the same framework as for ASTA. Equation (13) immediately gives necessary and sufficient conditions for departures see time averages: DSTA.

Theorem 5 [Conditions for DSTA]. *For all $B \in \mathcal{B}(S)$,*

$$p(B) = \pi^+(B) \Leftrightarrow q'(B) = \lambda.$$

Moreover, the following are equivalent:

1. $q'(B)$ is independent of B , $B \in \mathcal{B}(S)$;
2. $q'(B) = \lambda$, for all $B \in \mathcal{B}(S)$;
3. the frequency distributions $\{p(B), B \in \mathcal{B}(S)\}$ and $\{\pi^+(B), B \in \mathcal{B}(S)\}$ coincide.

Examples

Example 1 [Finite Capacity Model]. Consider an $M/G/1/K$ model with Poisson arrivals having rate λ , general service times distribution function and finite capacity K . Arrivals that find the system full are lost. Here arrivals that enter the system are not Poisson and PASTA does not hold. But the sample-path version of the covariance formula (Eq. 3) still holds; that is,

$$\bar{\lambda} \pi_n^- = \lambda_n p_n$$

where $\bar{\lambda}$ is the effective arrival rate, and π_n^- ; $n = 0, 1, \dots, K-1$ is the conditional arrival-time probability of arrivals that enter the system (i.e., the long-term fraction of arrivals, among those that join, that see the system in state n). It is well known that $\bar{\lambda} = \lambda(1 - p_K)$, and $\lambda_n = \lambda$ for $n = 0, 1, \dots, K-1$; and 0 otherwise, so $\lambda(1 - p_K)\pi_n^- = \lambda p_n$. Thus,

$$\pi_n^- = \frac{p_n}{1 - p_K}, \quad n = 0, 1, \dots, K-1,$$

which gives a relationship between π_n^- and p_n .

Example 2 [Machine Interference Model]. Consider the machine interference model with a finite population of size N and c exponential identical servers, each work at rate μ . When active, a machine time-to-failure is exponential with rate λ . Here, we have a state-dependent arrival rate $\lambda_n = (N - n)\lambda$ where n is the number of down machines. Note that the time between arrivals at the repair center are independent and exponentially distributed with state dependent rate $\lambda_n = (N - n)\lambda$, that is, the arrival process is not Poisson. Also, for this model, the LAA/LBA does not hold since $\lambda_n \neq \lambda$, so ASTA does not hold. However, relation (10) holds and reduces to

$$\bar{\lambda}\pi_n^- = \lambda_n p_n,$$

where $\bar{\lambda} = \lambda(N - L)$ is the effective arrival rate, and L is the mean number of down machines. Therefore,

$$\pi_n^- = \frac{N - n}{N - L} p_n. \quad (20)$$

Equation (20) gives a relationship between customer-average, π_n^- , and time-average, p_n , probabilities. It can be shown that

$$\pi_n^-(N) = p_n(N - 1), \quad (21)$$

when $\pi_n^-(N)$ is the arrival point probability with N customers in the system (e.g., up and down machines), and $p_n(N - 1)$ is the random observer (time average) probability

of n machines in the repair center with $N - 1$ customers in the entire system. Equation (21) says that an arrival sees the system time-average probability with one customer removed, that is, arrival does not see itself. It is worth noting that Equation (21) is known as the *arrival theorem* in closed Markovian queueing networks. Refer to the section on “*Queueing Theory and Queueing Networks*” in this encyclopedia for more discussion on queueing models.

STOCHASTIC FRAMEWORK

Here, we present ASTA using a stochastic framework based on the approach given by Melamed and Whitt [1] and Melamed and Yao [23], among others. The time-average and customer-average quantities are defined as expected values using stochastic Riemann–Stieltjes integrals.

Consider (X, N) as defined in the section titled “Setting and Problem Definition.” Recall that $X \equiv \{X(t), t \geq 0\}$ is any stochastic process, $N \equiv \{N(t), t \geq 0\}$ is any point process, the sequence of points $\{T_n, n = 0, 1, 2, \dots\}$ form an imbedded point process of X , and the imbedded state process is a stochastic sequence $X^N \equiv \{X^N(T_n^-), n \geq 0\}$, where for notational convenience $X^N(T_n^-) = X(T_n^-)$. The ASTA problem is concerned with finding sufficient and/or necessary conditions for which, in the limit, X and X^N converge to the same distribution. More specifically let

$$X(t) \xRightarrow[t \rightarrow \infty]{} X(\infty) \text{ and } X^N(T_n^-) \xRightarrow[n \rightarrow \infty]{} X^N(\infty),$$

where $\Rightarrow$ denotes convergence in distribution (weak convergence). Then, we say ASTA holds for (X, N) if

$$X(\infty) \stackrel{d}{=} X^N(\infty),$$

where $\stackrel{d}{=}$ denotes equality in distribution.

It is convenient to work with the transformed state process $U \equiv \{U(t), t \geq 0\}$, where $U(t) = f(X(t-))$ and f is a bounded

real-valued measurable function on $\mathcal{G}$. The function f is designed to extract the relevant information from the state description of X . For example, f can be an indicator function, so that the corresponding $U(t)$ can extract detailed stochastic information from X , whose limiting time averages are the state probabilities of X . Let

$$\begin{aligned}\bar{V}(t) &= E \left[\int_0^t U(s) ds \right] / t, \quad t \geq 0 \\ \bar{W}(t) &= \frac{E \left[\sum_{k=1}^{N(t)} U(T_k -) \right]}{E[N(t)]} \\ &= \frac{E \left[\int_0^t U(s-) dN(s) \right]}{E[N(t)]}, \quad t \geq 0,\end{aligned}$$

where $\bar{V}(0) = 0$, and $\bar{W}(t) = 0$, whenever $E[N(t)] = 0$. Then ASTA holds for the pair (U, N) if

$$\lim_{t \rightarrow \infty} \bar{V}(t) = \bar{V}(\infty) = \bar{W}(\infty) = \lim_{t \rightarrow \infty} \bar{W}(t)$$

provided one of the limits exist.

Remark. This framework is connected to the sample-path framework in the following sense. When we have weak convergence, then as $t \rightarrow \infty$

$$V(t) \Rightarrow V(\infty) = \bar{V}(\infty) = \lim_{t \rightarrow \infty} \bar{V}(t), \quad (22)$$

$$W(t) \Rightarrow W(\infty) = \bar{W}(\infty) = \lim_{t \rightarrow \infty} \bar{W}(t). \quad (23)$$

Equations (22) and (23) hold in a regenerative framework or in a stationary ergodic framework. (See the sections on “Point Processes” and “Renewal and Regenerative Processes” in this encyclopedia.) These frameworks suffice for most applications.

ASTA under the LBA Condition. The LBA weakens the LAA by providing a general necessary and sufficient condition for ASTA. The LBA condition requires the existence of a conditional stochastic intensity process, $\Lambda_c = \{\Lambda_c(t), t > 0\}$ of N given U .

Definition. [Conditional Stochastic Intensity]. The conditional intensity, $\Lambda_c(t)$, of N at t given $U(t)$, is a random variable

$$\Lambda_c(t) = \lim_{h \rightarrow 0} \frac{E[N(t+h) - N(t) | U(t)]}{h}, \quad t \geq 0$$

provided the limit exists.

A motivation for calling $\Lambda_c(t)$ an intensity process is offered by the fact that, if the interchange of limit and expectation operations is allowed, then

$$\begin{aligned}E[\Lambda_c(t)] &= E \left[\lim_{h \rightarrow 0} \frac{E[N(t+h) - N(t) | U(t)]}{h} \right] \\ &= \lim_{h \rightarrow 0} E \left[\frac{E[N(t+h) - N(t) | U(t)]}{h} \right] \\ &= \lambda(t),\end{aligned} \quad (24)$$

where $\lambda(t) \triangleq \frac{d}{dt} E[N(t)]$ is the unconditional intensity (rate) of $N(t)$. It is useful to think of $\Lambda_c(t)$ as the conditional (random) rate of a new arrival (point of N) at time t , given the state of the process is $U(t)$.

Remark. Let f be the identity function so that $U = X$. Let the state of X be discrete (e.g., number of customers in a queueing system) and assume that X is strictly stationary with known stationary distribution. Now given $X(t)$ in any set of states B , then $\Lambda_c(t) = q(B)$ w.p.1, in particular, if $X(t) = n$, $\Lambda_c(t) = \lambda_n$ w.p.1, where λ_n is first given in the section titled “Sample-Path Framework.”

Definition [LBA]. The pair (U, N) is said to satisfy the LBA, if U and Λ_c are point-wise uncorrelated, that is, $\text{cov}[U(t), \Lambda_c(t)] = 0$, for all $t \geq 0$.

The LBA weakens LAA by substituting a point-wise condition for an interval-based condition. This fact, together with stochastic intensity definition, imply that LBA is a local condition in the sense that the interactions between U and N (using Λ_c) need to be known only in an infinitesimal forward interval, and only through covariances which are a measure of linear dependence.

Lemma 3 [The Bias Formula]. *Suppose that*

1. *U and N are jointly stationary in the sense that*

$$\begin{aligned} & [U(t), N(t+h) - N(t)] \\ & \stackrel{d}{=} (U(t+s), N(t+s+h) - N(t+s)), \\ & t, s, h > 0 \end{aligned}$$

2. *Λ_c is well-defined and obeys Equation (24), so that*

$$E[\Lambda_c(t)] = \lambda, \quad t \geq 0,$$

where $\lambda = \lim_{h \rightarrow 0} \frac{N(h)}{h}$. Then, both $\bar{V}(t)$ and $\bar{W}(t)$ are independent of t and

$$\lambda(\bar{W}(t) - \bar{V}(t)) = \text{cov}[U(0), \Lambda_c(0)], t \geq 0. \quad (25)$$

The Bias formula (Eq. 25), also called *covariance formula*, gives a relation between the event averages $\bar{W}(t)$, time averages $\bar{V}(t)$, and the $\text{cov}[U(0), \Lambda_c(0)]$. Let X be a strictly stationary ergodic stochastic process, and let $U(t) = 1\{X(t) \in B\}$ where B is an arbitrary set in S . In this case, we show that Equation (25) is equivalent to the sample-path covariance formula (Eq. 10). By the ergodic theorem, it follows that

$$\begin{aligned} \bar{W}(t) &= \pi^-(B), \quad \bar{V}(t) = p(B), \text{ and} \\ E[U(0)] &= p(B) \quad \text{w.p.1.} \end{aligned} \quad (26)$$

Moreover,

$$\begin{aligned} \text{Cov}[U(0), \Lambda_c(0)] &= E[U(0)\Lambda_c(0)] - E[U(0)]E[\Lambda_c(0)] \\ &= E[U(0)E[\Lambda_c(0) | U(0)]] - \lambda p(B) \\ &= q(B)E[U(0)] - \lambda p(B) \\ &= q(B)p(B) - \lambda p(B). \end{aligned} \quad (27)$$

Substitute Equations (26) and (27) in Equation (25) to obtain (w.p.1)

$$\lambda \pi^-(B) = q(B)p(B),$$

which is the sample-path covariance formula given by Equation (10).

The following theorem and its proof are given in Ref. 1.

Theorem 6. [ASTA under Stochastic LBA]. *Suppose that the conditions of Lemma 3 hold for the pair (U, N) . Then $\bar{W}(\infty) = \bar{V}(\infty)$ iff LBA holds for (U, N) .*

Proof. Assume f is continuous, then

$$\begin{aligned} & E \left[\int_0^t U(s-) dN(s) \right] \\ &= E \left[\lim_{n \rightarrow \infty} \sum_{k=0}^{n-1} U \left(\frac{kt-}{n} \right) \right. \\ & \quad \left. \times \left\{ N \left(\frac{(k+1)t}{n} \right) - N \left(\frac{kt}{n} \right) \right\} \right] \\ &= \lim_{n \rightarrow \infty} \sum_{k=0}^{n-1} E \left[U \left(\frac{kt-}{n} \right) \right. \\ & \quad \left. \times \left\{ N \left(\frac{(k+1)t}{n} \right) - N \left(\frac{kt}{n} \right) \right\} \right] \\ &= \lim_{n \rightarrow \infty} \sum_{k=0}^{n-1} E[U(0)N(t/n)] \\ &= \lim_{n \rightarrow \infty} nE[U(0)E[N(t/n) | U(0)]] \\ &= E \left[U(0) \lim_{n \rightarrow \infty} nE[N(t/n) | U(0)] \right] \\ &= tE \left[U(0) \lim_{n \rightarrow \infty} \frac{E[N(t/n) | U(0)]}{t/n} \right] \\ &= tE[U(0)\Lambda_c(0)], \end{aligned}$$

where steps 1 and 2 are justified using Riemann–Stieltjes sum approach and Lebesgue-Dominated Convergence Theorem. Further details are given in Ref. 1. We also use the first condition in Lemma 3 in step 3, and calculus of conditioning in step 4. In the second-last step, convergence and uniform integrability remain unaltered on multiplication by the bounded random variable $U(0)$. Hence

$$\begin{aligned} \bar{W}(t) &= \frac{tE[U(t)\Lambda_c(t)]}{E[N(t)]} = \frac{tE[U(t)\Lambda_c(t)]}{E[\Lambda_c(t)]t} \\ &= E[U(t)], \end{aligned}$$

where we use *LBA* in the last step. But, by the definition of $\bar{V}(t)$ and the stationarity of U

$$\bar{V}(t) = E[U(t)].$$

So the result follows for continuous f . The extension to all measurable f , for which the expectations are well defined, is obtained by taking limits (24, pp. 7–9).

One can show that *ASTA* holds under the following *weak lack-of-anticipation assumption* (*WLAA*) given by Melamed and Whitt [1].

Definition. [*WLAA*]. The pair (U, N) is said to satisfy the *WLAA*, if for each $t \geq 0$ there exists $s_0 > 0$, such that $U(t)$ and $N(t+s) - N(t)$ are uncorrelated for all $0 \leq s \leq s_0$.

Note that *WLAA* is weaker than *LAA* and stronger than the *LBA*. Its primary advantage is that it may be easier than *LBA* to verify in certain applications. Moreover, the proof of *ASTA* under *WLAA* is straightforward.

REMARKS AND REFERENCES

Descloux [25], Strauch [26], Stidham [27], and Cooper [28] give elementary arguments for *PASTA*. In Ref. 6, Wolff proves *PASTA* in a general setting. In subsequent articles [1,10,11,14,22,29–33], the requirement that the point process be Poisson has been eliminated as a condition for events to see time averages, thus extending *PASTA*. In addition, the *LAA* assumption has been replaced by the weaker *LBA* [1,34,23,7]. Additional work on conditional *PASTA/ASTA* is found in Refs 21, 22 and 35.

In this article we present *PASTA* and related results, focusing on *PASTA* as given by Wolff [6], sample-path *ASTA* including conditional *ASTA* and reversed *ASTA* as given by Stidham and El-Taha [11,36], El-Taha and Stidham [7,14,19,20,37], and El-Taha [22]. We also cover *ASTA* in the expectation framework using stochastic Riemann–Stieltjes sum approach as given by Melamed and Whitt [1] and Melamed

and Yao [23]. We give several elementary examples to illustrate the issues discussed.

There are additional topics on *PASTA* and related problems that are not covered in this article. Below, we give a brief literature review of the martingale approach, the stationary framework approach, the filtered *ASTA* problem, *ASTA* in discrete-time, fluid *ASTA*, and applications to queueing networks among other topics.

Several authors use martingale theory to prove *PASTA* and related results. The martingale approach takes advantage of the martingale decomposition, stochastic integration, martingale *SLLN*, and stochastic intensities. It has the advantage of leading to general versions of *ASTA* without the stationarity assumptions. The martingale approach is used by Wolff [6] in proving *PASTA*. It is also used to extend *PASTA* to *ASTA* by eliminating the need for Poisson arrivals and replacing *LAA* by *LBA*. The list of authors include Melamed and Whitt [8], Melamed and Yao [23], Yao [38], Brémaud *et al.* [34], Bacelli and Brémaud [17], and Brémaud [9].

Rather than extending *ASTA* by weakening the conditions under which it holds, El-Taha and Stidham [19,20] show that the *ASTA* property can be strengthened under Wolff's original assumptions of Poisson arrivals and *LAA*. They prove that for any subset B , if *LAA* holds and the point process satisfies certain conditions (e.g., doubly stochastic Poisson), the B -process [i.e., the original point process restricted to the time spent by X in set B (B -time)] not only has the same intensity but is in fact a probabilistic replica of the original imbedded point process. In particular, the B -process is Poisson with intensity λ for every set B if (and only if) the original point process is Poisson with intensity λ . Stidham [27] gives an informal proof of this result for the special case of regenerative processes.

The stationary approach, which focuses on the underlying stochastic process being strictly stationary and views the *ASTA* problem as relating two expectations with underlying probability measures, $\mathbf{P}$, and its Palm-measure version, $\mathbf{P}^0$, via the Palm inversion formula, is used by König and Schmidt [32], Franken *et al.* [15], and again

by König and Schmidt [10]. Brémaud [9] connects the stationary framework and the martingale approach through Papangelou's lemma and Radon Nykodym derivative.

Given that *ASTA* holds, then anti-*PASTA*, a converse of *PASTA*, finds conditions under which the arrival process is Poisson. In a Markovian framework, the arrival process must be Poisson. For a discussion on the anti-*PASTA* problem, the reader may refer to Refs 3, 33, and 4. Using statistical sampling theory, Glynn *et al.* (39 and references therein) consider the issue of estimating customer averages and time averages.

Discrete time *ASTA* is given by Makowski *et al.* [40], using discrete-time martingales, and El-Taha and Stidham [7,19,20], using probabilistic arguments. Conditional and time-reversed *ASTA* results are given in Refs 19, and 21 among others. In Refs 7, and 20, weak convergence theory and limiting arguments are used to go from a discrete-time version to the continuous case. In the process, they extend the results of Ref. 19 to the case of a process with an imbedded cumulative input process, $A = \{A(t), t \geq 0\}$, which is assumed to be a Lévy process with nondecreasing sample paths. This framework allows for modeling fluid processes, as well as compound Poisson processes with noninteger increments.

Applications to queueing networks are considered in Refs 1, 7, 41 and references there in. In particular, in closed Markovian networks, it is shown that in equilibrium arrival-time probabilities are equal to time-average probabilities of the system state with one customer removed, that is, the customer in transit does not see itself. In Markovian networks, Melamed and Yao [23] show the equivalence of quasi-reversibility, *LBA*, and *ASTA*. El-Taha and Stidham [7] give a sample-path proof of the Arrival Theorem, and Serfozo [41] shows that moving units see time averages (*MUSTA*) holds for Markovian Jackson and Whittle networks.

PENALTY AND BARRIER METHODS

STEPHEN G. NASH

Systems Engineering and Operations
Research Department, George Mason
University, Fairfax, Virginia

Penalty and barrier methods solve a constrained optimization problem via a sequence of unconstrained problems. Under appropriate assumptions, the solutions of the unconstrained problems are guaranteed to converge to the solution of the original constrained problem. However, to obtain an accurate solution, the unconstrained problems will typically become ever more ill-conditioned, and special algorithmic techniques are needed to ensure good performance.

Penalty and barrier methods were important during the 1960s, but lost favor because of the difficulties associated with ill-conditioning (even though remedies were known at that time). However, interest in barrier methods revived in the 1980s in connection with the development of interior-point methods for linear programming [1]. Penalty and barrier methods are useful methods in their own right, but they also form the theoretical and practical underpinning to other important and widely used methods. In particular, penalty methods are the foundation for augmented Lagrangian methods, and barrier methods are the DNA of interior-point methods.

Penalty and barrier methods can be grouped together under the label of *penalization methods*. Penalty methods impose a penalty for violating a constraint, and barrier methods impose a penalty for approaching the boundary of an inequality constraint. Penalty methods usually approach the solution of the constrained problem via a sequence of infeasible points, and barrier methods approach the solution via a sequence of strictly feasible (interior) points. As a result, barrier techniques are typically only be applied to inequality constraints.

Penalty techniques are normally used to handle equality constraints, since standard approaches for applying penalty techniques to inequality constraints lead to unconstrained problems with discontinuous second derivatives. Penalty and barrier methods have much in common. Their convergence theories are similar, and the underlying structure of their unconstrained problems is similar.

Because of their influence on interior-point methods, barrier methods have received more attention than penalty methods. The discussion here also places more emphasis on barrier methods. Much of the theory for barrier methods can be replicated for penalty methods.

Here is an outline of the article. Sections titled “Barrier Methods,” “Penalty Methods,” and “Convergence” give an overview of barrier and penalty methods and their convergence properties. Sections titled “Ill-Conditioning” and “Stabilized Penalty and Barrier Methods” discuss the ill-conditioning associated with the methods. Sections titled “Extrapolation” and “Other Issues” describe algorithm enhancements to the methods. The section titled “Further Reading” gives suggestions for further reading.

BARRIER METHODS

Consider the nonlinear inequality-constrained problem

$$\begin{aligned} &\text{minimize } f(x) \\ &\text{subject to } g_i(x) \geq 0, \quad i = 1, \dots, m, \quad (1) \end{aligned}$$

where the functions f and g_i are assumed to be twice continuously differentiable. We assume that the feasible set has a nonempty interior; that is, there exists some point x_0 such that $g_i(x_0) > 0$ for all i . We also assume that it is possible to reach any boundary point by approaching it from the interior.

The barrier method is defined in terms of a function $\phi(x)$ that is continuous on the interior of the feasible set and becomes

Figure 1. Effect of the barrier term.

unbounded as the boundary of the set is approached from its interior

$$\phi(x) \rightarrow \infty \quad \text{as} \quad g_i(x) \rightarrow 0_+.$$

The most common choices are the logarithmic function

$$\phi(x) = -\sum_{i=1}^m \log(g_i(x))$$

and the inverse function

$$\phi(x) = \sum_{i=1}^m \frac{1}{g_i(x)}.$$

The *barrier function* is defined as

$$\beta_\mu(x) = f(x) + \mu\phi(x),$$

where μ is a positive scalar called the *barrier parameter*. The hope is that, as $\mu \rightarrow 0$, the minimizer of the barrier function approaches the solution of the original constrained problem. Figure 1 plots the logarithmic function $\phi(x)$ for the constraints $x \geq 1$ and $x \leq 2$ for various values of μ .

In discussing barrier methods, there is an expectation that the solution of the constrained optimization problem will lie on the boundary of the feasible region. If the solution is in the strict interior of the feasible region,

then (at least in a small neighborhood of the solution) the constraints are redundant, and the optimization problem shares many of the properties of an unconstrained problem. In the discussion below, the focus is on the behavior of barrier methods for problems where at least one constraint is binding at the solution.

It is usually necessary to solve a sequence of unconstrained minimization subproblems, rather than just solving one subproblem using a small value of the barrier parameter μ . That is, we solve

$$\text{minimize } \beta_{\mu_k}(x)$$

for a sequence $\mu_k \rightarrow 0$ of positive barrier parameters. For small values of μ , the problems are difficult to solve since the barrier function will have a singularity at the boundary of the feasible region. Thus, the barrier method is started with a larger value of μ , and μ is gradually decreased. If the solution of one unconstrained subproblem is used as the starting point for the next problem, these unconstrained minimization subproblems tend to be much easier to solve. If extrapolation is used to specify the starting point for the next problem (see below), algorithmic performance is further enhanced.

Because the original constrained problem is replaced by a sequence of unconstrained

subproblems, penalty and barrier methods have been called *sequential unconstrained minimization techniques* (SUMT) [2]. A related software package was developed around 1970, which was also called SUMT [3].

Under appropriate conditions on the optimization problem (1) and the barrier term $\phi(x)$, it is possible to prove convergence for barrier methods (see the section titled “Convergence”). Further, the sequence of barrier minimizers defines a differentiable curve $x(\mu)$ called the *barrier trajectory* [2]. The trajectory exists for the logarithmic barrier function, as well as for barrier terms $\phi(x)$ that satisfy appropriate convexity and monotonicity assumptions, provided that x_* is a regular point of the constraints that satisfies the second-order sufficiency conditions as well as the strict complementarity conditions. Path-following algorithms are based on this trajectory (see also **Central Path and Barrier Algorithms for Linear Optimization**). A point is *regular* if the gradients of the constraints binding at that point are linearly independent.

Barrier methods produce Lagrange multiplier estimates. Suppose that the barrier function has the form $\phi(x) = \sum_i \theta(g_i(x))$, for either the logarithmic barrier function, $\theta(y) = -\log(y)$, or for the inverse barrier function $\theta(y) = 1/y$. Let $x = x(\mu)$ be a minimizer of the barrier function for a specific value of μ . Setting the gradient of the barrier function to zero, we obtain

$$\nabla f(x) + \sum_{i=1}^m \mu \theta'(g_i(x)) \nabla g_i(x) = 0.$$

This can be re-written as

$$\nabla f(x) - \sum_{i=1}^m \lambda_i \nabla g_i(x) = 0,$$

where $\lambda_i = \lambda_i(\mu)$ is defined by

$$\lambda_i = -\mu \theta'(g_i(x)).$$

Thus, we have a feasible point $x(\mu)$ and a vector $\lambda(\mu)$ that satisfy the following relations:

$$\begin{aligned} \nabla f(x(\mu)) - \sum_{i=1}^m \lambda_i(\mu) \nabla g_i(x(\mu)) &= 0 \\ \lambda_i(\mu) g_i(x(\mu)) &= \mu, \quad i = 1, \dots, m \\ \lambda_i(\mu) &\geq 0, \quad i = 1, \dots, m. \end{aligned}$$

This is a perturbation of the first-order necessary conditions for optimality of the constrained problem. The only difference is that the complementary slackness conditions are perturbed, so that $\lambda_i(\mu) g_i(x(\mu))$ is equal to μ rather than to zero.

If x_* is a regular point of the constraints, then as $x(\mu)$ converges to x_* , $\lambda(\mu)$ converges to λ_* . The above results show that the points on the barrier trajectory, together with their associated Lagrange multiplier estimates, are the solutions to a perturbation of the first-order optimality conditions.

Another attractive property of barrier methods is that, if we use a convex barrier term such as the logarithmic barrier function or the inverse barrier function, then the barrier function is convex if the constrained problem is a convex optimization problem defined in terms of a convex objective function and concave constraint functions.

However, barrier methods suffer from ill-conditioning as the barrier parameter decreases. In most situations, the condition number of the Hessian of the barrier function tends to infinity as $\mu \rightarrow 0$. This is discussed in the section titled “Ill-Conditioning”. The reasons for this are visible in Fig. 1. If the constrained problem has a solution on the boundary of the feasible region then the barrier function will have a minimizer near the boundary of the feasible region. As the barrier parameter goes to zero, the distance from this minimizer to the singularity will go to zero as well.

This ill-conditioning influences the way the unconstrained problems are solved. Newton-type methods should be used, since their performance is less sensitive to the condition number of the Hessian than methods such as quasi-Newton or conjugate-gradient methods (see also **Non-linear Conjugate Gradient Methods**

and *Quasi-Newton Methods*). Within the unconstrained algorithm, special-purpose techniques have been developed for use in the context of barrier methods (see the section titled “Other Issues”).

Concerns about ill-conditioning caused barrier methods to fall into disfavor in the 1970s. However, interest in these methods was renewed in the 1980s with the development of Karmarkar’s method for linear programming [4] and the subsequent discovery that this method is a form of barrier method [5]. (When a barrier method is applied to a linear program with a unique solution, ill-conditioning does not arise.) Since then, there has been a renewed interest in barrier methods for nonlinear optimization, leading to the development of numerically stable algorithms (see the section titled “Stabilized Penalty and Barrier Methods”).

If the feasible region is unbounded, the unconstrained problem may not have a minimizer. This situation can occur only if the problem is nonconvex. For the following example,

$$\begin{aligned} &\text{minimize} && \frac{-1}{x^2 + 1} \\ &\text{subject to} && x \geq 1, \end{aligned}$$

the logarithmic barrier function is unbounded below in the feasible region, although it has a local minimizer that approaches the solution $x_* = 1$ as $\mu \rightarrow 0$.

Barrier methods require that the initial guess of the solution be strictly feasible. In general problems a strictly feasible point may not be known. It is sometimes possible to find an initial point by solving an auxiliary optimization problem. This is analogous to the use of a two-phase method in linear programming.

PENALTY METHODS

Penalty methods solve a sequence of unconstrained optimization problems where a penalty is imposed for violation of the constraints. As the penalty is increased, the iterates are forced toward the feasible region.

Penalty methods do not require the iterates to be strictly feasible. Thus, they

are suitable for problems with equality constraints.

Consider first, the equality-constrained problem

$$\begin{aligned} &\text{minimize} && f(x) \\ &\text{subject to} && g(x) = 0, \end{aligned}$$

where $g(x)$ is an m -dimensional vector whose i th component is $g_i(x)$. We assume that all functions are twice continuously differentiable.

The penalty for constraint violation will be a continuous function ψ satisfying

$$\begin{aligned} \psi(x) &= 0, && \text{if } x \text{ is feasible,} \\ \psi(x) &> 0, && \text{otherwise.} \end{aligned} \tag{2}$$

The best-known such penalty is the *quadratic-loss function*

$$\psi(x) = \frac{1}{2} \sum_{i=1}^m g_i(x)^2 = \frac{1}{2} g(x)^T g(x),$$

based on the 2-norm. Penalties can also be based on other norms, for example, exact penalty functions. The weight of the penalty is controlled by a positive *penalty parameter* ρ .

The *penalty function* is defined as

$$\pi_\rho(x) = f(x) + \rho\psi(x).$$

The penalty method solves a sequence of unconstrained minimization subproblems of the form

$$\text{minimize } \pi_{\rho_k}(x)$$

for an increasing sequence $\{\rho_k\}$ of positive values tending to infinity.

Penalty methods have many properties in common with barrier methods. First, under mild conditions, it is possible to guarantee convergence. Also, under appropriate conditions, the sequence of penalty function minimizers defines a continuous trajectory. In the latter case, it is possible to get estimates of the Lagrange multipliers in the solution. For

example, consider the quadratic-loss penalty function

$$\pi_\rho(x) = f(x) + \frac{1}{2}\rho \sum_{i=1}^m g_i(x)^2.$$

Its minimizer $x(\rho)$ satisfies

$$\begin{aligned} \nabla_x \pi_\rho(x(\rho)) \\ = \nabla f(x(\rho)) + \rho \sum_{i=1}^m \nabla g_i(x(\rho)) g_i(x(\rho)) = 0. \end{aligned}$$

Defining $\lambda_i(\rho) = -\rho g_i(x(\rho))$, we obtain that

$$\nabla f(x(\rho)) - \sum_{i=1}^m \lambda_i(\rho) \nabla g_i(x(\rho)) = 0.$$

If $x(\rho)$ converges to a solution x_* , which is a regular point of the constraints, then $\lambda(\rho)$ converges to the Lagrange multiplier λ_* associated with x_* [2].

Penalty functions also suffer from ill-conditioning. As the penalty parameter increases, the condition number of the Hessian matrix of $\pi_\rho(x(\rho))$ increases, tending to ∞ as $\rho \rightarrow \infty$. Therefore, the unconstrained minimization problems can become increasingly difficult to solve.

Penalty methods can be applied to problems with inequality constraints. Consider the problem

$$\begin{aligned} &\text{minimize } f(x) \\ &\text{subject to } g_i(x) \geq 0, \quad i = 1, \dots, m. \end{aligned}$$

In this case, it is possible to use the penalty

$$\psi(x) = \frac{1}{2} \sum_{i=1}^m [\min(g_i(x), 0)]^2.$$

This function has continuous first derivatives

$$\nabla \psi(x) = \sum_{i=1}^m [\min(g_i(x), 0)] \nabla g_i(x),$$

but its second derivatives can be discontinuous at points $\bar{x}$ where $g_i(\bar{x}) = 0$ for some i . Thus, one must exercise care when using Newton's method to minimize the function.

CONVERGENCE

We focus on the convergence of barrier methods when applied to the inequality-constrained problem. Convergence results for penalty methods can be developed in a similar manner [2].

Consider the problem

$$\begin{aligned} &\text{minimize } f(x) \\ &\text{subject to } x \in S, \end{aligned}$$

where

$$S = \{x : g_i(x) \geq 0, \quad i = 1, \dots, m\}.$$

Denote the interior of the feasible region by

$$S^0 = \{x : g_i(x) > 0, \quad i = 1, \dots, m\}.$$

The following theorem assumes that:

- (i) The functions f and $g_1, \dots, g_m$ are continuous on $\mathbb{R}^n$.
- (ii) The set $\{x : x \in S, f(x) \leq \alpha\}$ is bounded for any finite α .
- (iii) The set S^0 is nonempty.
- (iv) S is the closure of S^0 .

Assumptions (i) and (ii) imply that the function f has a minimum value f_* on the set S . Assumption (iii) is necessary to define the barrier subproblems. Assumption (iv) is necessary to avoid situations where the minimum point is isolated and does not have neighboring interior points. The barrier function is defined in terms of a continuous function ϕ that satisfies

$$\phi(x) \rightarrow \infty \quad \text{as } g_i(x) \rightarrow 0_+.$$

A proof of the theorem can be found in Ref. 6.

Theorem 1. *Suppose that a nonlinear inequality-constrained problem satisfies conditions (i)–(iv) above. Suppose that a sequence of unconstrained minimization problems*

$$\text{minimize } \beta_\mu(x) = f(x) + \mu\phi(x)$$

is solved for μ taking values $\mu_1 > \mu_2 > \dots > \mu_k > \dots$, where $\lim_{k \rightarrow \infty} \mu_k = 0$. Suppose also that the functions $\beta_{\mu_k}(x)$ have a minimum in S^0 for each k . Let x_k denote a global minimizer of $\beta_{\mu_k}(x)$. Then

- (i) $f(x_{k+1}) \leq f(x_k)$,
- (ii) $\phi(x_{k+1}) \geq \phi(x_k)$,
- (iii) the sequence x_k has a convergent subsequence,
- (iv) if $\{x_k : k \in \mathcal{K}\}$ is any convergent subsequence of unconstrained minimizers of β , then its limit point is a global solution of the constrained problem.

The theorem assumes that the barrier functions have a minimizer. This will be true if the set S is compact, or if the problem is convex [2].

It is also possible to prove convergence to a local minimum of the constrained problem if additional assumptions are made [2]. It is not true that every limit point of a sequence of local minimizers of the barrier function is a constrained minimizer [7].

ILL-CONDITIONING

In most cases, the barrier function becomes increasingly ill-conditioned as the barrier parameter μ decreases [8,9]. The analysis below is in terms of the logarithmic barrier function

$$\text{minimize } \beta_\mu(x) = f(x) - \mu \sum_{i=1}^m \log(g_i(x)),$$

but the result is true, in general, for other barrier and penalty functions. The results in the section titled “Stabilized Penalty and Barrier Methods” show how to overcome this ill-conditioning by deriving numerically stable formulas for the Newton direction in a barrier method.

The ill-conditioning can be observed by examining the formulas for the Hessian matrix of β :

$$\nabla_{xx}^2 \beta = \nabla^2 f - \mu \sum_{i=1}^m \frac{\nabla^2 g_i}{g_i} + \mu \sum_{i=1}^m \frac{\nabla g_i \nabla g_i^T}{g_i^2},$$

where we have written f in place of $f(x)$, and so on. Let $x(\mu)$ be an unconstrained minimizer of $\beta_\mu(x)$, and let $\lambda_i = \mu/g_i(x(\mu))$ be the associated Lagrange multiplier estimate. Then,

$$\nabla_{xx}^2 \beta = \nabla^2 f - \sum_{i=1}^m \lambda_i \nabla^2 g_i + \frac{1}{\mu} \sum_{i=1}^m \lambda_i^2 \nabla g_i \nabla g_i^T.$$

The term $\nabla^2 f - \sum_{i=1}^m \lambda_i \nabla^2 g_i$ is an approximation to the Hessian matrix of the Lagrangian of the problem. Its condition number reflects the conditioning of the Lagrangian Hessian for the original constrained problem.

The final term is the source of the ill-conditioning. If a constraint is binding at the solution of the constrained problem (and its corresponding Lagrange multiplier is not zero), then the ratio λ_i^2/μ tends to infinity as μ approaches zero. As a result, the Hessian matrix in general becomes increasingly ill-conditioned as the solution is approached. This structural ill-conditioning occurs even when the underlying constrained problem is well conditioned.

If a barrier method is applied to a linear programming problem, then the objective function and the constraint functions are all linear. Hence the Hessian of the barrier function simplifies to

$$\nabla_{xx}^2 \beta = \frac{1}{\mu} \sum_{i=1}^m \lambda_i^2 \nabla g_i \nabla g_i^T.$$

This matrix only involves the constraints in the linear program, and its conditioning corresponds to that of the underlying linear program. There is no ill-conditioning induced by the barrier method.

STABILIZED PENALTY AND BARRIER METHODS

In a number of settings, it is possible to implement a penalization method in such a way so as to avoid the effects of ill-conditioning. One approach is to use “stabilized” formulas for the search direction in a Newton-type method [9,10]. For example, consider using a

logarithmic barrier method to solve

$$\begin{aligned} & \text{minimize } f(x) \\ & \text{subject to } g(x) \geq 0. \end{aligned}$$

(The results can be extended to other penalty and barrier methods.) The ill-conditioning is avoided by using an approximate formula for the Newton direction for the barrier problem. This formula becomes more accurate as the barrier parameter goes to zero, that is, as the ill-conditioning becomes more severe.

For simplicity, assume that all the constraints are binding at the solution, and that all of these constraints have positive Lagrange multipliers. In practice, the techniques here are applied only to the binding constraints. The approach separates the Newton direction into two components, one in the null space and one in the range space of the constraint gradients. The approximations make it possible to compute both these components in a stable manner.

Let $A = \nabla g(x)^T$ be the Jacobian matrix of the constraints, and assume that A has full rank. Let Z be a basis matrix for the null space of A , where Z is obtained from an orthogonal QR factorization, so that

$$(Z \ A^T) \begin{pmatrix} Z^T \\ A_r^T \end{pmatrix} = I.$$

In addition, define the Lagrange multiplier estimates $\lambda_i = \mu/g_i(x)$ and the diagonal matrix D , whose i th diagonal entry is λ_i^2 . Finally, let $B = \nabla_{xx}^2 f$ be the Hessian of the barrier function, and let H be the Hessian matrix of the Lagrangian:

$$H = \nabla^2 f - \sum_{i=1}^m \lambda_i \nabla^2 g_i.$$

Then for small values of μ , it is possible to derive an approximation to the Newton direction p :

$$p = B^{-1} \nabla_x \beta \approx p_1 + \mu p_2,$$

where

$$\begin{aligned} p_1 &= -Z(Z^T H Z)^{-1} Z^T \nabla_x \beta, \\ \lambda &= A_r^T (H p_1 + \nabla_x \beta), \\ p_2 &= (Z(Z^T H Z)^{-1} Z^T H - I) A_r D^{-1} \lambda. \end{aligned}$$

The approximation is based on the inverse of $Z^T H Z$. This is a projection of the Hessian of the Lagrangian, which has no structural ill-condition, that is, no ill-conditioning due to the presence of the barrier parameter.

These formulas are expressed in terms of the inverse of $Z^T H Z$. This inverse matrix should not be formed. Instead a factorization should be computed. This factorization need only be computed once; back-substitution can be used to compute p_1 and p_2 . As $\mu \rightarrow 0$, it can be shown that the error in the approximate search direction is $O(\mu)$ [10].

If $Z^T H Z$ is positive definite at the point x , then these formulas produce a descent direction if the barrier parameter μ is sufficiently small. If $Z^T H Z$ is not positive definite, it is still possible to compute a descent direction by modifying the Hessian matrix using techniques adapted from Refs 11 and 12.

When solving an optimization problem with a large number of variables, it is often advantageous to use an iterative method (such as the linear conjugate-gradient method) to solve the systems of equations associated with $(Z^T H Z)^{-1}$. Consequently, these formulas require two runs of the iterative method. A related set of formulas can be derived that requires only one use of the iterative method and that is more suitable in this case [10].

Related results have been developed for more general interior-point methods. For example, if an interior-point method is developed by applying logarithmic barrier terms to bound constraints on the slack variables and the Lagrange multipliers, and if direct matrix factorizations are used, then the computations can be performed in a numerically stable manner [13,14].

EXTRAPOLATION

Extrapolation can be an important component of a penalization method. The discussion

here is based on using the logarithmic barrier method, but related results are valid for other penalization methods.

Given minimizers $x(\mu_k)$, $x(\mu_{k-1})$, $\dots$, of the barrier function for successive values of the barrier parameter, extrapolation approximates these minimizers using polynomial approximations parameterized by μ . For example, given $x(\mu_k)$, $x(\mu_{k-1})$, and $x(\mu_{k-2})$, a quadratic approximation is used. Then the initial guess $x_0(\mu_{k+1})$ for the new value of the barrier parameter is obtained from the polynomial approximation. If we use a linear approximation based on two successive values of μ then

$$x_0(\mu_{k+1}) = x(\mu_k) + \frac{\mu_{k+1} - \mu_k}{\mu_k - \mu_{k-1}} (x(\mu_k) - x(\mu_{k-1})).$$

Formulas for quadratic and cubic extrapolation are only slightly more elaborate.

Extrapolation is an inexpensive enhancement to a penalization method, but it can produce major improvements in the performance of the method [15].

The results here are based on the following assumptions:

- the third derivatives of the objective and constraint functions are continuous;
- the solution x_* of the constrained problem is a regular point;
- the reduced Hessian at x_* is positive definite; and
- strict complementarity holds.

Under these assumptions, x_* is an isolated local minimizer, and the corresponding Lagrange multipliers are unique [2]. Also, under these conditions, there exists an isolated twice-differentiable trajectory $x(\mu)$ converging to x_* , and the multiplier estimates converge to the Lagrange multipliers at the solution.

If linear extrapolation is used then it can be shown that:

- the initial guess $x_0(\mu_{k+1})$ is likely to be close to the solution of the new subproblem;

- the initial guess is likely to be feasible for the new subproblem; and
- the Newton step at the initial guess is likely to be feasible.

In contrast, if extrapolation is not used it can be shown that the gradient at this initial guess is not likely to be close to zero, and hence the initial guess is not close to the solution of the new subproblem [15]. Further, the Newton step at the initial guess is likely to be infeasible [16].

Related results on the barrier trajectory and extrapolation can be obtained with fewer assumptions than are made here [17,18]. It is also possible to apply extrapolation to penalty methods [19].

In degenerate cases, it may be appropriate to use alternative extrapolation formulas [20].

OTHER ISSUES

Penalization methods are based on solving a sequence of unconstrained problems. Because of the ill-conditioning, it is advisable to use a Newton-type method. In the context of penalization methods, it has been traditional to use a line search to ensure convergence of the unconstrained method. Thus, at each iteration of the unconstrained method the new estimate of the solution has been obtained via

$$x_{k+1} = x_k + \alpha p,$$

where $\alpha > 0$ is a scalar chosen to ensure that x_{k+1} is an improved estimate of the solution, and p is a descent direction for the penalty or barrier function at the point x_k .

Standard line-search algorithms are based on polynomial approximations. These are not ideal in the context of a penalization method, since the penalty or barrier term introduces a singularity or near singularity. For this reason, specialized line-search algorithms have been developed for use in this setting [21]. For a barrier method, this involves using a log-quadratic approximation in the line search:

$$\beta_\mu(x_k + \alpha p) \approx t_1 + t_2 \alpha + t_3 \alpha^2 - \mu \log(t_4 - \alpha),$$

where the coefficients $\{t_i\}$ are chosen to interpolate β and $\nabla\beta$ at two trial points. In addition, safeguards must be used to ensure that the trial points are strictly interior to the feasible region.

The performance of a barrier method can be improved by proper choice of the sequence of barrier parameters. The initial barrier parameter should not be too small (making the first unconstrained problem too hard to solve) nor too large (resulting in a large number of unconstrained problems). Also, if the barrier parameter is reduced too quickly or too slowly, the overall method will be less efficient. Techniques for initializing and adjusting the barrier parameter are discussed in Refs 10 and 22.

It is possible to prove complexity results for logarithmic barrier methods applied to convex optimization problems [23–25]. These results provide a bound on the number of iterations required to solve a barrier subproblem to within a tolerance $\epsilon = 2^{-M}$ in a number of operations that is polynomial in M and the problem dimensions. If polynomial algorithms exist to evaluate the gradient and Hessian, the overall algorithm for the barrier subproblem is polynomial in the dimensions of the optimization problem.

In general, barrier methods and penalty methods compute a sequence of unconstrained optima that approximate, but never equal, the solution of the underlying constrained problem. *Exact penalty methods* make it possible to solve the constrained problem *exactly* for a finite positive penalty parameter (see **Methods for Large-Scale Unconstrained Optimization**).

The ill-conditioning of penalty methods can be ameliorated by including multipliers explicitly in the penalty function. This idea is the basis of *augmented Lagrangian methods*. *Modified barrier methods* are an analogous extension of barrier methods [26].

Nonlinear primal-dual methods are also related to penalization methods. As discussed earlier, penalization methods produce Lagrange multiplier estimates that satisfy a perturbation of the optimality conditions for the constrained problem. In particular, they correspond to a perturbed set of complementary slackness conditions.

Primal-dual methods work explicitly with both primal and dual variables, and compute new estimates of the solution based on the perturbed optimality conditions. These methods were developed as an out-growth of interior-point (i.e., barrier) methods.

FURTHER READING

The most important reference on penalty and barrier methods is the book by Fiacco and McCormick (1968, reprinted 1990) [2]. It includes an extensive survey on the methods. A more recent discussion can be found in the paper by Wright [7]. For a history of these methods, see the report by Fiacco [27]. A general discussion of penalty and barrier methods, including examples and related methods, is in the book by Griva *et al.* [6].

PERCOLATION THEORY

JOHN WIERMAN

Department of Applied Mathematics and
Statistics, Whiting School of Engineering,
Johns Hopkins University, Baltimore,
Maryland

In physics, chemistry, biology, and materials science, percolation concerns the movement of fluid or clustering of particles in random media, when the nature of the medium has a substantial effect on the possible behaviors. The mathematical model of percolation, which involves randomly distributed connections in a graph, which represents the medium, is an alternative to diffusion models. Percolation theory has brought understanding to a wide range of scientific phenomena, and provides insight into more complicated models exhibiting phase transitions and critical phenomena. The study of percolation theory uses methods and techniques from probability, stochastic processes, and discrete mathematics. The reader may consult Grimmett [1] and Kesten [2] for the probabilistic perspective, Bollobás and Riordan [3] for the discrete mathematics perspective, and Sahimi [4], Hughes [5], Stauffer and Aharony [6], and Deutscher *et al.* [7] for scientists' perspectives and applications.

BOND AND SITE PERCOLATION MODELS

In a *bond percolation* model, each edge of an infinite graph G is declared to be open with probability p , $0 < p < 1$, independently, and closed otherwise. Denote the corresponding probability measure by P_p and the expectation with respect to P_p by E_p . The cluster C_v containing a vertex v of G is the set of vertices that can be reached from v through a path of open edges. The percolation probability function is $\theta_v(p) = P_p[|C_v| = \infty]$, where $|\cdot|$ denotes cardinality, represents the probability that v is in an infinite cluster. $\theta_v(p)$ is a nondecreasing and right-continuous function

for every v . If G is a connected graph, for any vertices v and w in G , $\theta_v(p) = 0$ if and only if $\theta_w(p) = 0$. The *critical probability* or *percolation threshold* of a connected graph G is defined by $p_c(G) = \sup\{p : \theta_v(p) = 0\}$, which is independent of the choice of v . Note that, by Kolmogorov's zero-one law, when $p > p_c$, there is an infinite open cluster in the lattice with probability one. The percolation threshold thus corresponds to a phase transition, such that the global behavior of the system is substantially different in the regions $p < p_c$ and $p > p_c$ of the parameter space. The model is said to be in the subcritical, critical, or supercritical phase if $p < p_c$, $p = p_c$, or $p > p_c$, respectively.

A *site percolation* model is defined similarly, with each vertex being open with probability p , with an edge declared to be open if both end points are open. Clusters, percolation probability function, and percolation threshold are defined analogously.

PERCOLATION THRESHOLD RELATIONSHIPS

Two simple relationships establish inequalities between percolation thresholds. If H is a subgraph of G , then $p_c(H) \geq p_c(G)$, for both site and bond models. If H is obtained by contracting a set of edges in G , then $p_c(H) \leq p_c(G)$ for bond models. Under broad conditions, these are strict inequalities, by a result of Aizenman and Grimmett [8] regarding the effect of enhancing one model by systematically adding connections based on local information.

The bond percolation model on graph G may be transformed into an equivalent site percolation model on the *line graph* of G , denoted by $L(G)$. Thus, $p_c^{\text{bond}}(G) = p_c^{\text{site}}(L(G))$. The vertices of $L(G)$ are the edges of G , with edges of $L(G)$ between two vertices if their corresponding edges have a common end-vertex. However, not every site model can be obtained in this manner, so the site percolation model is more general than the bond percolation model. Another relationship

between bond and site models is that, for any G , $p_c^{\text{bond}}(G) \leq p_c^{\text{site}}(G)$ [9].

There exist two important alternative definitions of the percolation threshold. A threshold $p_T(G)$ may be defined in terms of the expected cluster size: $p_T(G) = \sup\{p : E_p[|C|] < \infty\}$. Clearly, $p_T(G) \leq p_c(G)$ for any connected graph G . A third definition, p_S , in terms of probabilities of crossings of rectangular regions by open paths, was crucial to establishing exact percolation threshold values.

An infinite graph G is periodic if it can be embedded in $\mathbf{R}^d$ with $d \geq 2$, so that the graph is invariant under translations by d linearly independent vectors and the vertex set has no accumulation points. If so, we say that G has dimension d . Menshikov [10] and Aizenman and Barsky [11] independently proved the exponential decay of the probability distribution of $|C_v|$ when $p < p_c$, so that $p_T = p_c$ for periodic graphs in any dimension.

PERCOLATION THRESHOLD VALUES

The only exact percolation threshold solutions are for infinite trees and some two-dimensional periodic graphs. It is a major open problem to determine the exact percolation thresholds for additional graphs, and particularly for any lattice in three or higher dimensions.

Exact Values

The first exact solutions were for regular trees of degree d , obtaining the value $p_c = 1/(d-1)$ for both bond and site models by using branching process methods. Later, Lyons [12] characterized the percolation threshold of an arbitrary infinite tree.

Predictions of exact percolation thresholds were derived for the square, triangular, and hexagonal bond models and the triangular site model by an insightful heuristic approach by Sykes and Essam [13]. Their predictions were later confirmed, showing $p_c = 1/2$ for the square lattice bond model [64], $p_c = 2 \sin(\pi/18) \approx 0.347296$ for the triangular lattice bond model and $p_c = 1 - 2 \sin(\pi/18) \approx 0.652704$ for the

hexagonal lattice bond model [14], and $p_c = 1/2$ for the triangular lattice site model and the site model on any full-triangulated periodic lattice [2]. The bond thresholds of the bow tie lattice and its dual graph are the solutions $p_0 \in (0, 1)$ of the polynomial equation $1 - p - 6p^2 + 6p^3 - p^5 = 0$ and $1 - p_0$, respectively, where $p_0 \approx 0.404518$ [15]. Recent research has produced an approach for constructing an infinite class of graphs for which bond percolation thresholds may be exactly determined [16–18].

The solutions for bond models depend crucially on graph duality. Since dual graphs exist only for planar graphs, there are currently solutions only for two-dimensional lattices. Similarly, site model solutions rely on a matching property, which corresponds to duality for line graphs, and is valid only for two-dimensional lattices. Exact solution proofs also have relied heavily on symmetry properties of the graph. Evidently, symmetry conditions on the model are no longer necessary, due to results of Sheffield [19].

Since exact solutions do not exist for bond or site percolation on most lattice graphs of interest to physical scientists, considerable research has been focused on rigorous bounds, estimates, and approximations.

Bounds

Rigorous bounds for the threshold of a lattice graph are typically relatively far apart. For two of the most studied unsolved graphs, we have $0.556 < p_c < 0.679492$ for the square lattice site model [20,21] and $0.652703 < p_c < 0.743359$ for the hexagonal lattice site model [22], in which case the lower bound has not been improved since 1981. The substitution method [14,23] computes percolation threshold bounds for an unsolved lattice by comparing it to a solved lattice, comparing probability distributions of connections by stochastic ordering, obtaining $0.522197 < p_c < 0.526873$ for the kagomé lattice bond model and $0.739773 < p_c < 0.741125$ for the Archimedean $(3, 12^2)$ lattice [22].

Estimates

Over the years, many nonrigorous numerical estimations of percolation thresholds have been generated by simulating configurations on finite portions of the lattice, then extrapolating results from these to obtain the estimate. A variety of simulation approaches and algorithms for extrapolation are used, leading to some disagreement regarding error bounds. One established efficient method is due to Newman and Ziff [24,25], which produced an estimate of $0.59274621 \pm 0.00000013$ for the square lattice site percolation threshold. Riordan and Walters [26] developed a method for computing narrow confidence interval estimates with extremely high confidence levels, such as error probabilities of one per million, which does not use any extrapolation.

Approximation formulas [27,28], based on a small number of features of the graph, such as average degree and dimension, also provide estimates for percolation thresholds.

Critical Surfaces

In inhomogeneous percolation models, different directions or vertices in different locations have different probabilities of being open. For such models, there is a critical surface in the parameter space which corresponds to the percolation threshold in the homogeneous model. Only a few mathematically rigorous results have been established. For the square lattice, with each horizontal edge open with probability p_h and each vertical edge open with probability p_v , the critical surface is $p_h + p_v = 1$. The triangular lattice, with edges in the three directions open with probability parameters p_h , p_v , and p_d , the critical surface is $p_h + p_v + p_d - p_h p_v p_d = 1$. [1, Section 11.9].

CONTINUITY

The percolation probability function $\theta_v(p)$ can be successively approximated by the probability that v is connected to some vertex at distance n by an open path. Each such probability is a polynomial in p , so, being the

limit of nondecreasing continuous functions, $\theta_v(p)$ is right continuous. Thus, it is continuous at p_c if and only if the probability of an infinite open cluster is zero at p_c . With probability one, there are no infinite clusters at the percolation threshold for regular trees or for the periodic lattices in two dimensions, and this result also holds for periodic lattices in dimensions $d \geq 19$. However, for aperiodic graphs, there exist examples where there is an infinite cluster containing a vertex v at p_c with probability one.

UNIQUENESS

From reasoning based on Kolmogorov's zero-one law, for any value of p there may be zero, one, or infinitely many infinite open clusters in a graph. For $p > p_c$ there may be infinitely many infinite clusters, while for two-dimensional periodic graphs there is a unique infinite cluster. In fact, there exists a threshold $p_u \geq p_c$ such that for $p > p_u$ there is a unique infinite cluster [29,30]. For two-dimensional periodic lattices, $p_c = p_u$, but for trees $p_u = 1$, and for some other graphs $p_c < p_u < 1$. The concept of amenability is crucial for the study of uniqueness in percolation. The edge-isoperimetric constant of a graph G with vertex set V is $\kappa(G) = \inf_W \{|\partial W|/|W|\}$, where the infimum ranges over all finite connected subsets W of V and ∂W is the set of edges with one end point in W and one in $V \setminus W$. An infinite graph G is amenable if $\kappa(G) = 0$ and nonamenable otherwise. Partial results suggest the conjecture that if G is an infinite connected vertex-transitive graph, then $p_u > p_c$ if and only if G is amenable [31].

UNIVERSALITY AND CRITICAL EXPONENTS

It is generally believed that, although the value of the percolation threshold is related to the local structure of the graph, the nature and behavior of open clusters below, at, and above the threshold are invariant with respect to the local structure. The expected behaviors of various percolation functions are described in terms of power laws with the exponents referred to as *critical exponents*. The *universality principle* is that the critical

exponents depends only on the dimension of the lattice, and are independent of the detailed structure of the graph.

To describe the power law behavior, the notation $f(p) \approx |p - p_c|^\lambda$ means $\lim_{p \rightarrow p_c} \frac{\log f(p)}{\log |p - p_c|} = \lambda$ as $p \rightarrow p_c$. Similar notation may be used for functions of n as $n \rightarrow \infty$. The lattices are assumed to be periodic, with dimension d . The most common percolation functions, and the expected form of their power laws, are:

The percolation probability: $\theta(p) = P_p[|C| = \infty] \approx (p - p_c)^\beta$.

The mean finite cluster size: $\chi^f(p) = E_p[|C|, |C| < \infty] \approx |p - p_c|^{-\gamma}$.

The mean number of clusters per vertex: $\kappa(p) = E_p[|C|^{-1}]$, with power law $\kappa'''(p) \approx |p - p_c|^{-1-\alpha}$.

The cluster moments: $\chi_k^f(p) = E_p[|C|^k, |C| < \infty]$, with power laws

$$\frac{\chi_{k+1}^f(p)}{\chi_k^f(p)} \approx |p - p_c|^{-\Delta}.$$

The cluster volume: $P_{p_c}[|C| = n] \approx n^{-1-1/\delta}$.

The cluster radius: $P_{p_c}[\text{rad}(C) = n] \approx n^{-1-1/\rho}$.

The pair connectivity function:

$$P_{p_c}[0 \rightarrow x] \approx |x|^{2-d-\eta}.$$

The correlation length has several different definitions. Loosely, it represents the minimal distance beyond which the open clusters of two vertices are essentially uncorrelated. The notation and power law are $\xi(p) \approx |p - p_c|^{-\nu}$.

In almost all cases, it has not been proved that the limits defining critical exponents exist. For all these percolation functions, there are proofs of power bounds, instead of actual power laws, for many periodic graphs with $d = 2$ or sufficiently large d .

Based on heuristic derivations and simulation evidence, a number of *scaling relations* between the critical exponents are expected to be satisfied for graphs in any dimension: $2 - \alpha = \gamma + 2\beta = \beta(\delta + 1)$, $\Delta = \delta\beta$, and $\gamma = \nu(2 - \eta)$. In addition, in

dimensions $d = 2, \dots, 6$ there are anticipated *hyperscaling relations*: $d\rho = \delta + 1$ and $d\nu = 2 - \alpha$. Under the assumption that the limits defining the critical exponents exist, the scaling and hyperscaling relations (except that involving α) have been proved for a class of models in $d = 2$ [32] and the scaling relations for sufficiently high dimensions [33].

Physicists have predictions of the values of critical exponents when $d = 2$ or d is large [34–36]. Conjectured values for $d = 2$ are $\alpha = -\frac{2}{5}$, $\beta = \frac{5}{36}$, $\gamma = \frac{43}{18}$, $\delta = \frac{91}{5}$, and $\nu = \frac{4}{3}$. These values have been rigorously verified only for the triangular lattice site model [37]. It is widely believed that the critical exponents for lattices with dimension $d \geq 6$ have the corresponding values for a regular tree, which are $\alpha = -1$, $\beta = 1$, $\gamma = 1$, $\delta = 2$, $\rho = \frac{1}{2}$, $\eta = 0$, and $\nu = \frac{1}{2}$. The *lace expansion* has been extensively developed by Hara and Slade [33], and has been valuable for understanding percolation in higher dimensions. They proved many of the physicists' conjectures for bond percolation on the hypercubic lattices $\mathbb{Z}^d$ with $d \geq 19$. However, they can prove their results in any dimension $d > 6$ for *spread-out* models, which have edges between vertices, which are not the nearest neighbors in the lattice.

CONFORMAL INVARIANCE AND SCALING LIMIT

Percolation models on two-dimensional lattices are conjectured to have conformal invariance, in the sense that, if the lattice is rescaled so the spacing tends to zero, then certain limiting probabilities of crossing of regions are invariant under conformal mappings of the plane when the model is at criticality. Conformal invariance has been proved for the triangular site percolation model [38].

Stochastic Loewner Evolution [39–42], or Schramm–Loewner evolution, is a stochastic process of random planar curves generated by a differential equation with Brownian motion as the input. It is conjectured to be the scaling limit of various critical percolation models and other stochastic processes in the

plane, such as uniform spanning trees and planar loop-erased random walk. A parameter κ determines the distribution of the process, with $\kappa = 6$ believed to correspond to the scaling limit of the boundary of percolation clusters at criticality in two-dimensional models. This connection would yield proofs of the conjectured values for critical exponents in such cases, and has been proven to be correct for site percolation on the triangular lattice.

EXTENSIONS AND GENERALIZATIONS

A plethora of extensions of the classical percolation models have been developed, which allow a wide variety of phenomena to be modeled. We briefly introduce a few of the major alternative models to suggest the range of applications and behaviors.

Mixed Percolation

Mixed percolation models allow both vertices and edges, and sometimes faces also, to be open or closed at random. The most commonly treated case is “site-bond” percolation, in which both edges and vertices are randomized.

Directed Percolation

Directed percolation, sometimes called *oriented percolation*, randomly retains edges of a directed graph, usually to model the movement of a fluid in a random medium under the influence of a force such as gravity. A survey of methods and results is given in Ref. 43.

AB Percolation

The AB percolation model, also called *antipercolation*, was introduced as a model for gelation. Each vertex is labeled A with probability p and B otherwise, representing two possible chemicals or species that could occupy a site. An edge connects two vertices if they have opposite labels. Wierman and Appel [44] and Appel and Wierman [45] proved results concerning the existence and nonexistence of infinite AB percolation clusters on certain lattices.

Invasion Percolation

Invasion percolation is a dynamic process which models a fluid being pumped into a random medium under pressure, displacing other materials with least resistance. Each edge of the graph is independently assigned a random variable that is uniformly distributed on $(0, 1)$. A sequence of connected clusters is created by starting from one vertex and successively adding the edge on the boundary of the cluster which has the smallest value. For any $p > p_c$, the set of edges with a value less than p will contain an infinite component of the graph. Once the process reaches this component, it will never invade another edge with value greater than p . The principal result is that the empirical distribution function of the values of edges in the cluster converges to the uniform distribution on $(0, p_c(G))$ [46]. The version described above is called *nontrapping*, while a *trapping* model does not allow fluid to invade edges in regions that are already surrounded.

Continuum Percolation

It is important to model phenomena, which do not occur in a lattice structure, and a variety of models of continuum percolation have been introduced to do so. Common approaches are to place random objects, such as discs or balls in the space, or construct a random irregular graph from a set of random vertices located in the space. Bollobás and Riordan recently made a major advance, proving that the site percolation threshold is $1/2$ for the Delaunay triangulation constructed from the points of a homogeneous Poisson point process in the plane. Various models and results are described in the books by Meester and Roy [47], Bollobás and Riordan [3, Chapter 8], and Hall [48].

Fractal Percolation

Several models of fractal percolation have been proposed. A typical construction generates a random Cantor-like set by partitioning the unit square into N^2 subsquares, where $N \geq 2$, retaining each subsquare with probability p , then iterating this process for each retained subsquare. Although each point in the square is retained with probability zero,

depending on the parameters N and p it is possible to have an infinite set of points retained in the limit, and the limiting set may even contain a path which crosses the square with positive probability [49].

First-Passage Percolation

In the first-passage percolation model, each edge of the underlying graph G is assigned a nonnegative random variable which represents its travel time. Interest focuses on the shortest travel time between two vertices over the infinite set of paths available. Ergodic theory for subadditive processes is used to prove that a limiting velocity exists in each direction from the origin, and that a limiting shape exists for the set of vertices that are reached from the origin by time t , as $t \rightarrow \infty$ [50,51].

Bootstrap Percolation

The bootstrap percolation process is a cellular automata started from a random configuration. As an example, consider an $n \times n$ grid of the square lattice, with vertices occupied randomly with probability p , and, at each stage, an unoccupied vertex becomes occupied if it has at least two occupied neighbors. For p sufficiently large, every vertex eventually becomes occupied. A remarkably precise result of Holroyd [52] states shows that the asymptotic behavior of the threshold satisfies $\lim_{p \rightarrow 0} p \log n = \frac{1}{18} \pi^2$. A typical application is to advance the fluid flow front in porous media when the state of a location is dependent on the nearby pores and microstructure.

Dynamical Percolation

In dynamical percolation [53], time dynamics are added to the classical bond or site percolation model. In the dynamical bond model, for fixed p , edges of the underlying graph change between open and closed states according to independent two-state Markov processes. Changes to the open state occur at rate p , while changes to the closed state occur at the rate $1 - p$. The unique stationary distribution of the model is ordinary bond percolation with parameter p . Interest centers on the differences in behavior from the classical model.

Additional Models

The proliferation of variations has been extensive, including models named ρ -percolation, self-destructive percolation, clique percolation, last passage percolation, gradient percolation, and line-of-sight percolation. The different types of models may be used in various combinations, such as directed first-passage percolation.

CONNECTIONS TO OTHER MATHEMATICAL TOPICS

Random Graph Theory

The classical Erdős-Rényi random graph model $G_{n,p}$ is defined similarly to the bond percolation model, starting with the complete graph on n vertices and retaining each edge independently with probability p , $0 < p < 1$. Interest also focuses on the existence of thresholds at which the behavior of the graph changes dramatically. There has been a very substantial and fruitful exchange of concepts and methods between random graph theory and percolation theory. The theory is developed in [54–56].

Correlation Inequalities

Percolation theory stimulated the development of correlation inequalities, particularly the FKG inequality [57] and BK inequality [58], which are useful in reliability theory, random graph theory, and statistical mechanics.

Interacting Particle Systems

Interacting particle systems model a collection of objects on a lattice which may change the state according to the states of their neighbors [59,60]. A common application is the spatial epidemic processes. Percolation techniques have played an important role in the development of the theory.

Statistical Mechanics

Percolation is in the class of Potts models, corresponding to setting the parameter $q = 1$. The Ising model for ferromagnetism corresponds to the Potts model with $q = 2$.

Percolation research has provided insight and methods to advance understanding of these models and the more general the Fortuin–Kasteleyn random cluster models [61].

Subadditive Processes

The theory of subadditive stochastic processes originated in first-passage percolation, and the ergodic theorem for subadditive processes [62,63] plays a crucial role in the proof of the asymptotic shape theorem. Subadditive processes have found extensive applications in probability, stochastic processes, and statistics.

PERFECT BAYESIAN EQUILIBRIUM AND SEQUENTIAL EQUILIBRIUM

AKIRA OKADA
Graduate School of Economics,
Hitotsubashi University,
Tokyo, Japan

INTRODUCTION

A subgame perfect equilibrium as defined by Selten [1] is a fundamental equilibrium concept for an extensive-form game. Specifically, it is effective for games with perfect information in which every player knows perfectly all past moves; in other words, every information set consists of a single node. The concept, however, is too weak for games with imperfect or incomplete information. A subgame perfect equilibrium may prescribe irrational player behavior after some unexpected deviations from the equilibrium strategies have occurred. To overcome this difficulty of a subgame perfect equilibrium, a concept in noncooperative game theory termed refinements of the Nash equilibrium has emerged and is the focus of active research.

The crux of the research is to define rational behavior for players when their moves are reached unexpectedly on the play of a game. The standard approach is to use the Bayesian decision theory developed by Savage [2], assuming that when a rational player makes a choice under uncertainty, he constructs a personal probability judgment about each uncertain event and maximizes the expected payoff with respect to these probabilities. Two important equilibrium concepts in this approach are those of a (weak) perfect Bayesian equilibrium defined by Fudenberg and Tirole [3] and of a sequential equilibrium defined by Kreps and Willson [4]. Roughly, these equilibrium concepts require that every player's strategy be optimal for his corresponding information set with respect to his probability judgment ("belief") about what

actions have been chosen on the previous play and players' future strategies. This condition, however, is not sufficient. In order for an equilibrium to be sensible, a strategy profile must be "consistent" with players' beliefs.

A (weak) perfect Bayesian equilibrium satisfies a weak notion of consistency that players' beliefs should be computed from the Bayes rule whenever possible, that is, for all information sets reached with positive probabilities by the equilibrium play. However, it allows any probability distribution for players' beliefs for information sets off the equilibrium play. Thus, the (weak) perfect Bayesian equilibrium may be too weak for a broad class of games and may not even be a subgame perfect equilibrium. A sequential equilibrium satisfies a stronger notion of consistency using the "trembling-hand" approach underlying a perfect equilibrium as introduced by Selten [1].

The rest of the article is organized as follows: The section titled "Preliminaries" gives some preliminaries on an extensive-form game; the section titled "Perfect Bayesian Equilibrium" reviews a (weak) perfect Bayesian equilibrium; the section titled "Sequential Equilibrium" reviews a sequential equilibrium; and the final section concludes.

PRELIMINARIES

We first present some preliminaries on extensive-form games. The definitions follow Selten [1]. For more detailed explanations, see the other sections. An *extensive-form game* is described as a set of five elements $\Gamma = (K, P, U, p, h)$. The *game tree* K is a finite directed tree with origin o . Let Z be the set of all terminal nodes in K , and X be the set of all other nodes. Each node $x \in X$ represents a decision point (move) whereby some player makes a choice. An edge connecting two nodes represents a choice. Let $S(x)$ be the set of all choices for x . A unique sequence of nodes and edges that connects o to a node x is called the *path* to x . The *player partition*

$P = (P_0, P_1, \dots, P_n)$ is a partition of X . P_0 is the set of *chance moves* whereby choices are made according to random mechanisms. $P_i (i = 1, \dots, n)$ is the set of moves by player i .

The *information partition* U is a collection $U = (U_1, \dots, U_n)$ where each U_i is a partition of P_i . An element $u \in U_i$ is called the *information set* of player i . Every information set u satisfies: (i) every path intersects u at least once, and (ii) all nodes in u have the same number of choices. When player i makes a choice for $x \in u$, he does not distinguish all other nodes in u from x . Owing to (ii), it can be assumed with no loss of generality that $S(x) = S(y)$ for every x and y in u given some suitable identification of choices. The set of choices for u , $S(u)$, is defined by $S(x)$ where $x \in u$.

The *probability assignment* p assigns to every $x \in P_0$ a completely mixed probability distribution over $S(x)$. The *payoff function* u assigns a payoff vector $h(z) = (h_1(z), \dots, h_n(z))$ to every terminal node $z \in Z$.

A *behavioral strategy* of player i is a function b_i that assigns to every $u \in U_i$ a probability distribution b_{iu} over the set $S(u)$ of choices at u . Let B_i be the set of behavioral strategies of player i . For a behavioral strategy profile $b = (b_1, \dots, b_n)$ of players, the probability of a terminal node z is defined and denoted by $\rho(z|b)$. The *expected payoff* $H_i(b)$ for player i for b is defined by $H_i(b) = \sum_{z \in Z} \rho(z|b) h_i(z)$.

A subtree K' of K is called a *subgame* of Γ if it is true for every information set u of Γ such that u never contains two nodes, one in K' and the other outside K' , simultaneously. Γ is a subgame of itself. A subgame of Γ is called *proper* if it is not equal to Γ . A behavioral strategy profile b for Γ naturally induces a behavioral strategy profile on its subgame. The expected payoff for a behavioral strategy profile in a subgame can be defined in the same way as for Γ .

We now define the two fundamental solution concepts for an extensive-form game.

A Nash equilibrium is defined by Nash [5] and a subgame perfect equilibrium is defined by Selten [1].

Definition 1. (i) A behavioral strategy profile $b^* = (b_1^*, \dots, b_n^*)$ for Γ is a *Nash equilibrium* of Γ if for every $i = 1, \dots, n$ and

for every $b_i \in B_i$, $H_i(b^*) \geq H_i(b_i, b_{-i}^*)$ where (b_i, b_{-i}^*) is the strategy profile obtained from b^* by replacing b_i^* with b_i . (ii) A behavioral strategy profile $b^* = (b_1^*, \dots, b_n^*)$ for Γ is a *subgame perfect equilibrium* of Γ if it induces a Nash equilibrium on every subgame of Γ .

PERFECT BAYESIAN EQUILIBRIUM

The notion of a subgame perfect equilibrium is very effective for eliminating unreasonable Nash equilibria in games with perfect information whereby every information set consists of only one node. Unfortunately, this is not the case in games with imperfect information.

To illustrate this point, consider a three-person extensive-form game Γ^1 with imperfect information in Fig. 1 in Ref. 1. In Γ^1 , all three players have two choices. A payoff vector assigned to each terminal node represents payoffs for players 1, 2, and 3 from top to bottom. In the game, player 1 first makes a choice. If he chooses R_1 , then player 2 makes a move knowing the choice made by player 1. If player 2 chooses R_2 , then the game ends and all players receive payoffs 1. If player 2 chooses L_2 , then the game proceeds to a move by player 3. Player 3 has another opportunity to make a choice if player 1 chooses L_1 at the

Figure 1. A game in which all Nash equilibria are subgame perfect.

start of the game. The information set of player 3, containing two nodes, reflects the fact that player 3 does not know which node is reached on his move.

Γ^1 has two Nash equilibria in pure strategies, (L_1, R_2, R_3) and (R_1, R_2, L_3) . To demonstrate why (L_1, R_2, R_3) is a Nash equilibrium, it suffices to know that the choice by every player is optimal for the strategies of all other players. Player 1's choice L_1 is optimal to player 2's choice R_2 and player 3's choice R_3 since he receives payoff 3 from L_1 larger than payoff 1 from R_1 . Note that player 2's information set is not reached when player 1 chooses L_1 . Thus, player 2 is indifferent between R_2 and L_2 . R_3 is player 3's optimal choice to L_1 . Readers can confirm for themselves that (R_1, R_2, L_3) is also a Nash equilibrium.

Since Γ^1 has no proper subgame, every Nash equilibrium of Γ^1 is a subgame perfect equilibrium. That is, (L_1, R_2, R_3) and (R_1, R_2, L_3) are subgame perfect equilibria. Are both equilibria reasonable? Consider (L_1, R_2, R_3) . When player 2 has a move unexpectedly, he receives payoff 1 from R_2 . Player 2, however, can receive a higher payoff 4 by choosing L_2 , expecting that player 3 will choose his equilibrium strategy R_3 (player 3 does not know that player 2 deviates from R_2). The Nash equilibrium (L_1, R_2, R_3) prescribes a nonoptimal strategy R_2 for player 2. If player 2's move is actually reached, it is optimal for him to choose L_2 . Realizing this fact, player 1 will choose R_1 and will receive payoff 4 higher than his equilibrium payoff 3. Clearly, this Nash equilibrium cannot be regarded as reasonable.

The game Γ^1 shows that the notion of a subgame perfect equilibrium is weak for an extensive-form game with imperfect information. A subgame perfect equilibrium may include disequilibrium (nonpayoff-maximizing) behavior for players on moves not reached by the equilibrium play with positive probability. The easiest way to overcome this difficulty of a subgame perfect equilibrium is to impose the following condition:

- (P) A subgame perfect equilibrium should prescribe player behavior that maximizes

his expected payoff after an information set containing a single node is obtained.

In Γ^1 , (R_1, R_2, L_3) satisfies this condition and (L_1, R_2, R_3) does not. Although condition (P) is effective for information sets with single nodes, it is not effective in general.

Consider a two-person game Γ^2 in Fig. 2 in Ref. 4. Γ^2 has a subgame perfect equilibrium (R_1, R_2) for pure strategies. This equilibrium satisfies (P) since player 1's choice R_1 is optimal for player 2's choice R_2 . However, it is not rational for player 2 to choose R_2 because his optimal choice is L_2 , regardless of which node is reached in the information set.

The game Γ^2 poses a general question: how should we define rational behavior for information sets with more than one node? According to Bayesian decision theory, when a rational player makes a choice under uncertainty, he constructs a personal probability judgment about each uncertain event and maximizes the expected payoff with respect to these probabilities. Such a subjective probability judgment is called a player's *belief*.

Formally, a system of beliefs is a function $\mu: X \rightarrow [0, 1]$ such that $\sum_{x \in u} \mu(x) = 1$ for each information set u . $\mu(x)$ is interpreted as the probability the player assigns to x when u is reached. An *assessment* is a pair

Figure 2. A subgame perfect equilibrium may prescribe irrational behavior for information sets with more than one node.

(μ, b) , where μ is a system of beliefs and b is a behavioral strategy profile. Given an assessment (μ, b) and an information set u of player i , the *conditional probability* $\rho(z|\mu, b)$ over Z_u , the set of all terminal nodes z reachable from some nodes in u , is well defined. Then the *conditional expected payoff* for player i for (μ, b) at u is defined as $H_{i,u}(b|\mu) = \sum_{z \in Z_u} \rho(z|\mu, b)h_i(z)$.

What are the types of conditions needed for an assessment (μ, b) to be a solution of an extensive-form game? Obviously, it is necessary that it should satisfy *sequential rationality*: the strategy of every player starting from his information set must be optimal, that is, maximize his conditional expected payoff after the information set, given his belief and all other players' strategies.

Sequential rationality is not sufficient for an assessment (μ, b) to be an equilibrium since a system μ of beliefs must be "consistent" with a behavioral strategy profile b . What belief should a rational player have? One reasonable condition is that a player's belief must be computed from the Bayes rule whenever possible. If an information set is reached with positive probability, then a player's belief about which node is reached in it should be equal to the conditional probability given by the Bayes rule. Then, what is his belief when an information set has zero probability ex ante? What is a reasonable belief when a player finds that his information set is reached unexpectedly? A possible answer is that we simply allow any probability distribution in such a case. This is a weak version of the perfect Bayesian equilibrium in Ref. 3.

Definition 2. An assessment (μ^*, b^*) is a (weak) *perfect Bayesian equilibrium* of an extensive-form game Γ if the following conditions hold for every $i = 1, \dots, n$.

1. *Sequential Rationality.* For every information set $u \in U_i$ and every $b_i \in B_i$, $H_{i,u}(b^*|\mu^*) \geq H_{i,u}(b_i, b_{-i}^*|\mu^*)$.
2. *The Bayes Rule.* For every $u \in U_i$ and every $x \in u$,

$$\mu(x) = \frac{\rho(x|b^*)}{\sum_{y \in u} \rho(y|b^*)},$$

if $\sum_{y \in u} \rho(y|b^*) > 0$ where $\rho(y|b^*)$ is the probability that a node $y \in u$ is reached under b^* . If $\sum_{y \in u} \rho(y|b^*) = 0$, then $\mu(x)$ can be any probability distribution over u .

The conditions of a perfect Bayesian equilibrium are simple and easy to check. For example, a Nash equilibrium (R_1, R_2, L_3) of Γ^1 is a perfect Bayesian equilibrium. Since the information sets of players 1 and 2 contain single nodes, their beliefs are trivial and they satisfy sequential rationality. Equilibrium strategy L_3 of player 3 satisfies sequential rationality if his belief assigns to the right node a probability greater than $2/3$. Since the information set of player 3 is not reached on the equilibrium play, any belief is allowed.

Owing its simplicity, the notion of a (weak) perfect Bayesian equilibrium is frequently applied to economic models, and specifically to games with two sequential moves. However, it may not work well if a game has more than two sequential moves. The game Γ^3 in Fig. 3 illustrates this point. In Γ^3 , player 1 has two information sets and player 2 has one information set. Consider a behavioral strategy profile $b = (R_1 r_1, R_2)$. An assessment (μ, b) is a weak perfect Bayesian equilibrium if the belief μ assigns probability

Figure 3. A weak perfect Bayesian equilibrium may not be subgame perfect.

1 to the left node in the information set of player 2. Since the latter information set is not reached on the play of b , such a belief is admissible. By contrast, b is not a subgame perfect equilibrium. Namely, the strategy profile (r_1, R_2) induced by b is not a Nash equilibrium of the subgame starting at the player 1's second information set.

The game Γ^3 shows that it is necessary to impose a consistency between players' strategies and their beliefs for information sets not reached by the equilibrium play. This task is achieved using the concept of a sequential equilibrium.

SEQUENTIAL EQUILIBRIUM

Kreps and Wilson [4] define the notion of consistency for an assessment in an extensive-form game using the trembling-hand approach introduced by Selten [1]. The basic idea is as follows: If an information set of a player is reached unexpectedly on a game play, then the player imagines that some previous players may have deviated from their equilibrium strategies by "mistake" before his move. Then, according to his imagination about possible mistakes on the past play, the player constructs his belief about which node has been reached in the information set using the Bayes rule. Formally, a consistent assessment is defined as follows:

Definition 3. An assessment (μ^*, b^*) of an extensive-form game Γ is *consistent* if there exists some sequence $\{(\mu_n, b_n)\}_{n=1}^\infty$ of assessments such that:

1. Each b_n is a completely mixed behavioral strategy profile, that is, it assigns a strictly positive probability to every choice in Γ , and μ_n is the system of beliefs generated from b_n by the Bayes rule; and
2. (μ_n, b_n) converges to (μ^*, b^*) as $n \rightarrow \infty$.

It should be noted that every information set is reached with a positive probability under a completely mixed behavioral strategy profile. Thus, the Bayes rule can be

applied for every information set. A sequential equilibrium is a weak perfect Bayesian equilibrium satisfying consistency in Definition 3.

Definition 4. An assessment (μ^*, b^*) of an extensive-form game Γ is a *sequential equilibrium* if it is both consistent and sequentially rational.

To understand the consistency criterion for a sequential equilibrium, consider again the game Γ^1 in Fig. 1. We show that a Nash equilibrium $b^* = (R_1, R_2, L_3)$ is a sequential equilibrium with the system μ^* of beliefs where μ^* assigns probability 1 to single nodes in the information sets of players 1 and 2, and probability 2/3 to the right node in the information set of player 3. It is easy to see that the assessment (μ^*, b^*) is sequentially rational. To demonstrate that (μ^*, b^*) is consistent, consider a completely mixed behavioral strategy profile $b_n = (b_{1,n}, b_{2,n}, b_{3,n})$ such that $b_{1,n} = (1 - \epsilon_n, \epsilon_n)$, $b_{2,n} = (1 - 2\epsilon_n, 2\epsilon_n)$, and $b_{3,n} = (\epsilon_n, 1 - \epsilon_n)$, where the first component in $b_{i,n}$ ($i = 1, 2, 3$) represents the probability assigned to choice R_i . Suppose that each $\epsilon_n > 0$ and ϵ_n converges to 0 as n goes to infinity. From $(b_{1,n}, b_{2,n})$, we can compute the belief of player 3 for his information set using the Bayes rule. This assigns probability

$$\mu_n(x) = \frac{2(1 - \epsilon_n)\epsilon_n}{2(1 - \epsilon_n)\epsilon_n + \epsilon_n} = \frac{2(1 - \epsilon_n)}{2(1 - \epsilon_n) + 1},$$

to the right node x in the information set of player 3. $\mu_n(x)$ converges to 2/3 as n goes to infinity. This demonstrates that (μ^*, b^*) is consistent. The construction of the completely mixed behavioral strategy profile b_n means that when his information set is reached unexpectedly, player 3 believes that players 1 and 2 may have chosen L_1 and L_2 mistakenly, and moreover that the error probability for player 2 is twice as great as that for player 1.

Kreps and Wilson [4] prove that a sequential equilibrium has the following properties.

Theorem 1. *For every extensive-form game with perfect recall by Kuhn [6], there exists at least one sequential equilibrium.*

Theorem 2. *If an assessment (μ^*, b^*) is a sequential equilibrium, then b^* is a subgame perfect equilibrium.*

The concept of a sequential equilibrium has prompted active research into noncooperative game theory to scrutinize “credible” beliefs for off-equilibrium play in Ref. 7–9. Although the definition of consistency by Kreps and Wilson [4] is mathematically simple, it may be too weak for some classes of extensive-form games.

Consider the game Γ^4 in Fig. 4 in Ref. 10. (R_1, R_2) is a sequential equilibrium with the belief of player 2 that assigns probability 1 to the right node in his information set. Note that player 2’s information set is not reached when player 1 chooses R_1 . It is evident that player 2’s belief is consistent with player 1’s strategy R_1 . If his information set is reached unexpectedly, player 2 believes that choice of M_1 is infinitely more likely than L_1 . In fact, any belief of player 2 can be consistent with player 1’s strategy R_1 (the proof is left to readers). However, it can be claimed that player 2’s belief above is not intuitively reasonable. The reason is as follows: M_1 is dominated by R_1 , that is, it gives player 1 a lower payoff than R_1 , regardless of which action player 2 chooses. If we take the view that a rational player should not choose any dominated action, then it is not sensible for player 2 to believe that player 1 has chosen the dominated action M_1 . When his information set is reached, player 2 should conclude that player 1 has chosen L_1 , not M_1 . Then his optimal choice will be L_2 . By this reasoning, we can say that (R_1, R_2) is not a sensible equilibrium and that the only sensible equilibrium is (L_1, L_2) .

In non-cooperative game theory, the question as to what a credible belief should be for an information set for off-equilibrium play has not been fully answered yet. The answer seems to depend on how a player should interpret players’ possible deviations ex post, whereas such events are impossible ex ante. Selten’s trembling-hand approach supposes players’ random mistakes by some unspecified psychological mechanisms. Other approaches discussed in the literature are to

Figure 4. A sequential equilibrium may be too weak.

suppose that different players may have different theories about how to behave or that players deviate with a certain intention and send some signals by doing so. The latter approach is called *forward induction*.

Finally, there is also active research into weakening the concept of a sequential equilibrium. Fudenberg and Tirole [3] present the notion of perfect Bayesian equilibrium that satisfies sequential rationality and a weaker notion of consistency without the trembling-hand approach.

CONCLUSION

We have reviewed two important refinement concepts of a subgame perfect equilibrium for an extensive-form game with imperfect information, a (weak) perfect Bayesian equilibrium and a sequential equilibrium. These equilibrium concepts are defined in terms of a pair comprising a behavioral strategy profile and a system of beliefs so that they satisfy sequential rationality and consistency. A (weak) perfect Bayesian equilibrium requires a weak consistency that the Bayes rule should be applied whenever possible. A sequential equilibrium requires a stronger consistency that uses the trembling-hand approach of Selten [1].

PERFECT INFORMATION AND BACKWARD INDUCTION

MAREK M. KAMINSKI
Department of Political Science and
Institute for Mathematical Behavioral
Science, University of California,
Irvine, California

The origins of backward induction (BI) are unclear. Zermelo [1] was the first to analyze winning in chess, but his method of analysis was based on a different principle than BI [2]. Reasoning based on BI was implicit in Stackelberg's [3] construction of his alternative to the Cournot equilibrium. As a general procedure for solving two-person zero-sum games of perfect information, BI appeared in the von Neumann and Morgenstern's 1944 founding book [4], p. 117]. It was used to prove a precursor of Kuhn's Theorem for chess and similar games. The von Neumann's exceedingly complex formulation was later clarified and elevated to a high theoretical status by Kuhn's work [5], especially Corollary 1], Schelling's [6] ideas of incredible threats, and Selten's [7] introduction of subgame perfection. In the late 1970s, BI went under critical fire when the chain-store paradox, Centipede, and other games questioned its universal appeal [8,9]. The criticism, supported by experimental evidence, greatly diminished the appeal of backward induction in some games.

DESCRIPTION OF THE BACKWARD INDUCTION PROCEDURE

A bum approaches you in a dark street, displays a gun, and asks for a \$100 donation. If you give him the money (M), the game ends. If you refuse his offer (R), he promises to shoot *himself* (see the left panel in Fig. 1 BUM).

The solution to the game based on BI would proceed as follows: First, let us consider what happens when you refuse to give the money to the bum. He chooses between

shooting himself and receiving the payoff of 0 versus not shooting and receiving 1; thus, he selects N . In the first case, you receive 0 and in the second case you receive 2. You can anticipate his action N and assume that refusing automatically gives you 2 (since he will not shoot himself), while giving the money to the bum gives you 1. You choose not to give him the money.

In your reasoning, you used a small part of the original game, where the bum's subgame is substituted with the payoffs resulting from his best choice (Fig. 1, right panel). By analyzing the smaller game, you choose R , and the strategy profile chosen by BI is (R, N) . The game was solved by running backward with respect to the decision making order. First, the last decision in the game was analyzed and then the reasoning turned to the first decision.

The main idea behind the BI algorithm is to keep reducing games to smaller games, and to keep in mind the partial solution obtained in the process of reduction. Slightly more formally, the algorithm may be described for any finite extensive form game of perfect information in the following way.

Start at some of the final decision nodes, D (let us assume that the player who moves at D is j). Then select an action that offers the highest payoff to j at D (let us call such an action a). The existence of at least one payoff-maximizing action is guaranteed by the finite character of the game. Let us assume that there is just a single action that leads to the highest payoff. (If there are many actions with such a property, the reasoning is conducted separately for all of them and the more general algorithm applicable to such a case is slightly more complex.) Next, a new game is constructed by substituting D and the branches following D in the old game with the payoff vector assigned to a . The intuition behind the reduction is that all players in the game may predict that, once D is reached, j will correctly choose the action a that maximizes his payoff. Thus, once we reach D , the payoff vector assigned

Figure 1. The game of Bum (left panel) and Bum reduced after applying the first step of backward induction (right panel).

to a will automatically follow. This means that there is no point in considering D and the following actions. The game may be now simplified. One has to remember the action a that j selected at D since this particular action becomes a part of the game's solution.

The reasoning described above, that is, the reduction of the original game to smaller games, is repeated until a final single vector of payoffs is obtained. What will result from the reduction is a strategy profile that consists of all best actions obtained at some stage of reduction procedure. Those actions (including the actions that will not be actually played) constitute a backward induction strategy profile (BISP). It can be proved that the final strategy profile is the same for all possible reductions of the original game.

When there are two or more actions available, one has to create separate partial strategy profiles for all such actions that include all previously obtained actions. Then the reasoning proceeds in a similar fashion for every partial strategy profile.

NASH EQUILIBRIUM, INCREDIBLE THREATS AND SUBGAME PERFECTION

In the game of Bum, the strategy profile selected by BI was (R, N) . It is easy to see that this particular strategy profile constitutes a Nash equilibrium of this game (see **Nash Equilibrium (Pure and Mixed)**). If Player 1 switches to M , then her payoff goes down from 2 to 1. If Player 2 switches to S , his payoff goes down from 1 to 0. This example illustrates the first important property of BI: it selects only Nash equilibria.

(R, N) is not the only Nash equilibrium. Another one is (M, S) in which you offer the bum his donation; if you did not, he would

shoot himself. This equilibrium has one flaw: it does not look reasonable. It is based on an *incredible threat* that the bum would shoot himself once you refuse the donation. However, if you refuse, the bum has no incentive to carry out the threat. He would be better off by abandoning his threat.

The concept of incredible threat was introduced by Schelling [6]. The interplay between credible versus incredible threats was at the center of the hugely popular movie "Dr. Strangelove." BI cleverly disregards Nash equilibria that are based on incredible threats. Thus, BI offers a *refinement* of the Nash equilibrium, that is, for every game, BISP are a subset of all Nash equilibria that excludes from consideration equilibria that are intuitively "unreasonable." This is the second important property of BI. However, while being very intuitive, the idea of "incredible threat" turned out to be difficult to formalize. Moreover, BI eliminates other unreasonable Nash equilibria that are not based on incredible threats.

Let us assume that our bum has an option of shooting himself also when he receives the \$100 donation. Thus, the game does not end with the donation M but two more actions are available to the bum once he receives the donation: s and n (see Fig. 2 Crazy Bum).

In Crazy Bum, there are three Nash equilibria. (M, nS) and (R, nN) intuitively correspond to (M, S) and (R, N) in the original Bum. The third equilibrium, (R, sN) , is the weirdest one. In this equilibrium, you refuse to make the donation, and the bum does not shoot himself. However, he would shoot himself if you gave him the money! The behavior associated with the strategy profile (R, sN) makes even less sense than the one associated with the equilibrium based on an

Figure 2. The game of Crazy Bum.

incredible threat. And yet, (R, sN) is a Nash equilibrium.

The ideas incorporating incredible threats and other unreasonable equilibria were formalized by Selten with his solution concept of subgame perfect equilibrium [7]. Briefly, a strategy profile is subgame perfect equilibrium (SPE) if it is a Nash equilibrium in all subgames of a game, including the game itself. The requirement imposed by the Nash equilibrium on players is strengthened. Since a subgame can be imagined as a small self-enclosed game, in an SPE, players are required to play Nash equilibrium strategies at every decision node that could demarcate such a new smaller game. In the game of Bum, SPE requires that the Nash equilibrium in this game must have an additional property: in the subgame, when the bum makes his decision, he must choose an action that is better for him. This is precisely the requirement of eliminating incredible threats. In the game of Crazy Bum, SPE requires additionally that the bum must choose the best action after receiving the money.

It is relatively easy to prove that, for finite games of perfect information, BI and subgame perfection represent the same solution concept, that is, the sets of BISP and SPE are always identical. It can also be proved that this coincidence is in fact true for all games (according to a very general definition of a game) and all pure strategies [10]. Thus, the final important fact about BI is that it selects precisely the same set of strategy profiles as subgame perfection. At the same time, for many games it offers an effective algorithm of finding all SPEs, which is simpler than looking for SPEs directly from its definition.

VARIANTS

In the version of BI described earlier, every smaller game was obtained by removing a single set of branches that originated at the same decision node. This version of BI can be generalized and multiple branches can be removed simultaneously.

Consider the following two-player game: you start with choosing a positive integer that is not greater than ten. Next, your opponent chooses another integer that is greater than your number, but the difference is again not greater than 10. Then you choose another integer by adding to the previous number no more than ten, and so on. The player who is the first to say a number at least equal to 100 is the winner.

Who can claim victory in this game?

The reader may be willing to pause reading at this point and to try solving the game. In fact, the problem is not easy to solve until we apply BI. Then it becomes trivial:

The game is finite, and there is a winner in each specific play. Let us assume that the winning player made the total of n moves. She could say 100 if she said 89 in her move $n - 1$ since her opponent must say at least 90 and no more than 99. Thus, saying 89 is a sufficient condition for guaranteeing herself the victory.

By the same logic, a player could say 89 in move $n - 1$, she could say 78 in her move $n - 2$, and so on. The strategy to say consecutively 1, 12, 23, 34, 45, 56, 67, 78, 89, 100 regardless of the other player's choices guarantees a player winning. Thus, Player 1—who can start by saying “one”—can claim the victory.

Our solution obtained above clearly uses some form of BI. However, a more careful examination of the reasoning reveals that, in every step that takes us backwards, we remove more than just one decision node with corresponding branches. For instance, in the last step, after Player 1 says 89, Player 2 could say any number from 90 to 99 before Player 1 says 100. All such numbers represent one or more subgames. Thus, in our solution, we remove several subgames and several decision nodes at the same time. More specifically, we remove an entire complex

subgame that starts with the decision node following Player 1 saying 89.

Kaminski [10] implies that the above-described procedure is a legitimate extension of BI. Moreover, we can substitute any disjoint subset of subgames with the SPE payoffs in those subgames and obtain all SPEs in the original game in the same way as it happens with the original BI. This property becomes critical for games with infinite actions or of infinite length.

In the Ultimatum game, Player 1 chooses a number $x \in [0, 1]$ that represents the amount Player 1 wants to keep. Next, Player 2 makes the choice. She may accept the proposed division and receive $1 - x$, while Player 1 receives x , or she may reject it, in which case both players receive zero. The BI reasoning stipulates that Player 2 accepts any positive amount offered to her and that she is indifferent between accepting and rejecting zero. Thus, in SPE, Player 1 can propose only one, that is, everything for himself. The unique SPE in the ultimatum game is when Player 1 proposes one and Player 2 accepts any proposed amount, including zero.

The ultimatum game provides a simple illustration of the usefulness of BI outside of the realm of finite games. However, as discussed later, its predictive power is questionable. A better example of how the strategic intuition motivating BI allows gaining insights into an important political process is provided by the Agenda-setter game [11].

Two players, the Agenda setter A and the Legislator L, have Euclidean preferences in the issue space $[0, 3]$ and the ideal points $a = 0$ and $l = 2$, respectively. The status quo is $q = 3$. First, A proposes a policy $x \in [0, 3]$. Next, L exercises his veto power and chooses the final law from $\{x, q\}$, that is, either rejects (R) or agrees that the new policy be implemented (P). (Euclidean preferences define the payoffs as negatives of distances between a player's ideal point and the point in the issue space resulting from the strategy profile.)

To solve the game by BI, let us consider L's problem. Since the distance between l and q is 1, L prefers any new policy that is closer to l than 1; is indifferent between 1 and q ; and prefers q to any policy that is farther from l than 1. Thus, the best action responding to

$x \in [0, 1]$ is R ; the best answer to $x \in (1, 3)$ is P ; and for 1 both R and P are best answers. Now, let us consider A's problem. Anticipating L's response, A does not try to impose on L his ideal point, zero. He offers a policy that is closer to L's ideal point. The policy that is closest to A's ideal point and acceptable for L is 1. Thus, the unique outcome selected by BI is 1.

The Agenda-setter game explains a vast variety of strategic interactions taking place between the two chambers of parliament, parliaments, and supreme courts or presidents endowed with veto power, and so on, all over the world. While the calibration of issue spaces is a perennial problem, the universally observed phenomenon is that policy proposals take into account the preferences of the relevant veto players, and incorporate them into the offer.

CRITICISM

It is sometimes argued that in the ultimatum game, zero offers to the second player happen infrequently, and that players sometimes reject even positive amounts offered to them. However, the phenomenon may be explained not by the failure of BI to predict the outcome correctly, but rather by an incorrect specification of player payoffs in the experimental setting. The actual player payoffs may not only represent the amount that the players receive but also their feelings of fairness. When monetary rewards are small, as is the case in experiments, such feelings may seriously disturb the payoffs.

There are more serious problems with BI than its alleged failure to predict the outcome of the ultimatum and similar games. One may ask a simple question: What would happen with games like chess if all potential players were using BI in a consistent fashion? The answer is now truly troublesome: nobody would be willing to play a game. Perfect "backward inductionists" would always reach the same outcome. We have not learned so far whether it would be the victory of whites or blacks, or possibly a tie. What we do know is that in the world of perfect BI this determinate outcome would be well known and there would be no thrill from playing

the game. Similarly, all board or computer games of perfect information would instantly lose their appeal.

Obviously, people play chess and other games and reach various outcomes, which implies that at least some of them are not perfect backward inductionists.

In fact, there are quite simple games in which real-world players practically always deviate from the principles of BI. The deviations can be attributed to the complexity of decision environment, the presence of a small amount of incomplete information, or making assumptions about other players' reasoning not being perfectly compatible with BI. In games such as the chain-store paradox [8,9], competing firms may engage in behavior that contradicts the predictions drawn from BI. Consider the following game of Centipede (see Fig. 3 Centipede)

Player 1 begins. She can continue or she can stop. When she stops, both players receive the payoff of one. Then Player 2 faces a similar choice, and so on. A player who continues increases the payoff of the other player by two and decreases his own payoff by one, assuming that the other player would immediately stop. The unique BI solution to the Centipede is that Player 1 stops immediately (and that both players would stop at any moment of the game). However, one can notice that, if both players continue for just one round, they will always get at least as much as in the unique BI equilibrium (Player 1's payoff may drop to 1 while Player 2's payoff will always remain strictly higher than 1). If they continue for at least two rounds, they always get strictly more. In fact, in experiments players typically recognize the rewards coming from

a longer play and practically always continue until nearly the end of the game. (When demonstrating Centipede to his students, the author of the present article started with ten-rounds-long Centipedes and payoffs in real dollars. He quickly learned that the three-round version is sufficient to illustrate the problem and, needless to say, much less expensive!)

The epistemic literature on BI puts emphasis on player expectations. If Player 2 gets the chance to make her first move, she understands that Player 1 deviated from the reasoning prescribed by BI and did not stop. Thus, she may be willing to assume a substantial probability of another future deviation, and continue herself. But Player 1 can predict this reasoning of Player 2 and continue in the first round precisely because of such expectations.

Another problem of BI is also closely connected to the insufficient power of subgame perfection to eliminate unreasonable Nash equilibria. In the game shown below, there are three Nash equilibria (see Fig. 4).

Player 2 is indifferent between the two available actions L and R . The version of BI that is suitable for such cases would admit all three Nash equilibria: When 2 selects R , 1 selects a (equilibrium (a, R)); When 2 selects L , 1 selects either a or b (equilibria (a, L) and (b, L)). However, the third equilibrium (b, L) does not seem reasonable since the strategy b of player 1 is weakly dominated by his strategy a . One can hardly justify the use of this particular strategy by Player 1—even if b performs against L as well as a , why would he take the risk that Player 2 will choose R and will bring him a lower payoff? Player 2 is

Figure 3. The game of Centipede with three rounds.

Figure 4. A game with BISP that includes a weakly dominated strategy.

indifferent between L and R and Player 1 has no reason to believe that one will be chosen over another.

The unreasonably looking strategy profile (b, L) can be eliminated by the solution concept such as perfect equilibrium that is more restrictive than SPE [12].

INCORRECT USES OF BI

A popular BI anecdote tells the following story. The prison warden announces to a game theorist on death row: "Today is Sunday. You will be executed during the next week. You will be very surprised when the day of your execution comes." The game theorist thinks for a while and responds with relief: "In such a case, I won't be executed at all!"

What was his reasoning?

It is easy to reconstruct the poor game theorist's way of thinking. He cannot be executed on next Sunday, the last day his execution is possible, since in such a case he would not be surprised at all. Thus, since next Sunday is impossible, the last possible day of execution is Saturday. But it is also impossible to hold the execution on Saturday since, once it comes, it would be the last possible day for the execution because Sunday had already been eliminated. But this means that our game theorist would certainly expect execution on Saturday and would not be surprised. By going backward, we can eliminate every single day in the next week. The execution is not possible.

How did the story end? The game theorist was executed on Wednesday and he was very surprised!

The flaw in the backward reasoning described above is that it does not refer to any specific game (the reader may try to construct a game that would correspond to the story). Instead, it uses some concepts that do not even have formal equivalents in extensive form games, such as "being surprised." Thus, while there is some superficial similarity to BI, the backward reasoning is not BI. There is some reduction applied and the inference goes backward, but this is

about where the similarity between the two types of reasoning ends.

PERFORMANCE BOUNDS IN QUEUEING NETWORKS

MICHAEL H. VEATCH
Department of Mathematics,
Gordon College, Wenham,
Massachusetts

Efficient scheduling of queueing networks is an important topic in applications including manufacturing systems and communication networks. However, because of the intractability of their optimal control formulations and the complexity of optimal policies, most analysis has focused on simple policies or stability. Given these limitations, one useful approach has been to compute bounds on the performance of any policy. Computing a lower bound on a cost measure allows analysts to also bound the suboptimality of a proposed heuristic policy, which can be very useful in the development of heuristics. Computing an upper bound on the performance of a specific policy or class of policies can be useful in establishing stability or establishing the robustness of a class of policies.

Most of the bounds we discuss are based on a Markov decision process (MDP) formulation of the network control problem with exponentially distributed interarrival and service times. We also restrict attention to sequencing control, that is, each station decides at each time what class of customer to serve, or possibly to idle. The network structure is an open multiclass network with probabilistic routing (see *Multiclass Queueing Network Models*). The objective is to minimize the long run average number of customers in the system, or average cost, where cost is a linear function of the number of customers of each class. Closed reentrant lines are also briefly considered.

The bounds considered are, to varying degrees, computable. Some are in closed form, while others require solving a linear program (LP) or computing average cost under a simple policy. Another body of research has developed theoretical bounds on the error in

some computable average cost estimate. For example, Refs 1–3 present bounds on the error using approximate LP techniques for discounted cost problems. They also bound how far the cost achieved by the approximate policy is from the optimal cost. Both bounds are instructive but involve quantities that cannot be computed, such as the stationary distribution under the optimal policy.

The bounds are presented in a roughly historical order. The sections titled “Achievable Region Method,” “Approximate Linear Programming,” and “LP Upper Bounds” cover LP methods and some nonlinear programming extensions of them. The approximate LP method involves approximating the dynamic programming value function. A dual relationship between these methods demonstrates that certain approximate LP bounds are tighter. The section titled “LP Upper Bounds” modifies the LPs in the first two sections. The next section is titled “Pathwise Bounds.” The section titled “Lyapunov Function Bounds” interprets the approximate LP inequalities as the condition for a Lyapunov function and describes bounds on expected cost and tail probabilities for general Lyapunov functions.

QUEUEING NETWORK SCHEDULING

An open multiclass network is defined as follows (see *Multiclass Queueing Network Models*). Customers arrive and move through different classes before exiting the network. There are n customer classes and m stations, each of which serves one or more classes. Let $X_i(t)$ be the number of class i customers at time t , including any that are being processed. Class i customers are served by station $\sigma(i)$. Each station can serve only one customer at a time. Unless otherwise noted, we assume that exogenous arrivals at each class are independent Poisson processes with rates α_i and processing times are independently exponentially distributed with mean $1/\mu_i$ in class i . Both the processing times and the routing of a customer depend on the class (not the station) in a multiclass network.

Routing may be probabilistic: $P = [p_{ij}]$ is the routing matrix with p_{ij} the probability that a customer finishing service at class i will be routed to class j , independent of all other history. We let p_{i0} represent the probability that a customer finishing service at class i leaves the system; it is equal to $1 - \sum_j p_{ij}$.

The network is open in that every customer eventually leaves with probability 1. For open networks, the effective arrival rate to class i , λ_i , is the unique solution to the traffic equation

$$\lambda = \alpha + P^T \lambda.$$

The utilization of server σ is $\rho_\sigma = \sum_{i:\sigma(i)=\sigma} \lambda_i / \mu_i$. We assume that $\rho < 1$.

We wish to bound the performance of any control policy. The performance measure is long-run average cost, J , where the cost rate is $c^T x$ in state $X(t) = x$. The minimum value of J for all policies is denoted by J^* . Often the objective is to minimize the expected number of customers in the system, in which case $c = \mathbf{1}$. For these system performance measures, the queue discipline within a class does not matter. Instead, each server must decide which job class to work on at each time, or possibly to idle. Preemption is allowed. Let $u_i(t) = 1$ if class i is served at time t and 0 otherwise. The infinite horizon objective and exponential distributions imply that there is an optimal policy that is stationary and Markov. Hence, we consider only such policies, writing $u(t) = u(X(t))$. In a slight abuse of notation, we also let u denote an action. The allowable actions in state x are

$$\mathcal{A}(x) = \left\{ u : \sum_{i:\sigma(i)=\sigma} u_i \leq 1 \quad \text{for all } \sigma, u \leq x, \right. \\ \left. u_i = 0 \text{ or } 1 \right\}.$$

The first constraint says that a server can only work on one class at a time; the second prevents serving an empty buffer. Also, let $\mathcal{A}$ be all the allowable actions. Because $\rho < 1$, there exists a stabilizing policy, so J^* is finite.

To uniformize the process, introduce an independent Poisson process with rate μ_i for

each class i , representing potential service completions. A discrete-time Markov chain is constructed by observing the system at each arrival and potential service completion. A potential service completion is an actual service completion if that class is being served. Assume that the potential event rate $\sum_{i=1}^n (\alpha_i + \mu_i) = 1$ so that these rates are also transition probabilities. In the sequel $X(t)$, $t = 1, 2, 3, \dots$ denotes the discrete-time Markov chain.

The network is called a *reentrant line* if all customers follow the same cycle through the network, say visiting classes in the order $1, 2, \dots, n$. In this case, $\alpha = (\alpha_1, 0, \dots, 0)$, $p_{i,i+1} = 1$ for $i < n$, $p_{n0} = 1$, and $\lambda_i = \alpha_1$ for all i . Customers may reenter a station, $\sigma(i) = \sigma(j)$ for some $i \neq j$. We will briefly consider closed reentrant lines. A network is called *closed* if no customers arrive or depart and a certain number of customers, N , circulate endlessly. In a closed reentrant line, all customers follow the same cycle through the network and are routed from class n to class 1. Each class has the same long run throughput, which will also be called λ .

ACHIEVABLE REGION METHOD

The idea of the achievable region method is to write flow balance equations, which hold in steady-state under any stable policy, for certain functions of $X(t)$. In particular, quadratic test functions lead to linear equations in the expected queue length and some auxiliary variables. These define a region in the space of expected queue lengths which contains the region that can be achieved under various policies, known as the *achievable region*. Minimizing average cost over the larger region bounds the average cost of any policy. This method was introduced in Ref. 4 for single-station and in Ref. 5 for multistation networks. One quadratic function, the square of workload, is used in Ref. 6 for stability and in Ref. 7 to bound performance. Many extensions are developed in Ref. 8, such as considering specific buffer priority policies, machine failure models, probabilistic routing, and general distributions. Extensions to higher-order test functions, other performance measures, and nonlinear constraints are made in Ref. 9.

Introduce the variables

$$z_{ij} = E[u_i(t)X_j(t)], \quad x_j = E[X_j(t)],$$

where the expectation is with respect to the stationary distribution for some policy u . The policy must have a unique stationary distribution and finite second moments, $E[X_i(t)^2] < \infty$, with respect to this distribution.

The logical constraint $\sum_{i:\sigma(i)=\sigma} u_i(t) \leq 1$ for each server σ leads to the constraint

$$\sum_{i:\sigma(i)=\sigma} z_{ij} - x_j \leq 0 \quad \text{for all } j, \sigma. \quad (1)$$

Let $\Delta X_i(t) = X_i(t+1) - X_i(t)$. Defining $\Delta(X_i X_j)$ similarly, under the stationary distribution, we must have

$$E[\Delta(X_i(t) X_j(t))] = 0 \quad \text{for } i \leq j.$$

This constraint can be thought of as stationarity with respect to a general quadratic test function [8, Section 2]. Now,

$$\begin{aligned} E[\Delta(X_i(t) X_j(t))] &= E(\Delta X_i(t) X_j(t)) \\ &\quad + E(X_i(t) \Delta X_j(t)) \\ &\quad + E(\Delta X_i(t) \Delta X_j(t)). \end{aligned}$$

Taking expectations with respect to the transition and then with respect to $X(t)$,

$$\begin{aligned} E(\Delta X_i(t) X_j(t)) &= \alpha_i x_j + \sum_{k=1}^n \mu_k p_{ki} z_{kj} - \mu_i z_{ij}, \\ E(\Delta X_i(t) \Delta X_j(t)) &= \begin{cases} 2\lambda_i(1 - p_{ii}) & \text{if } i = j \\ -(\lambda_i p_{ij} + \lambda_j p_{ji}) & \text{otherwise} \end{cases} \end{aligned}$$

with the conventions that $x_0 = z_{i0} = z_{0j} = 0$. The stationarity constraints, after dividing by 2 on the diagonal, are

$$\begin{aligned} \alpha_i x_i + \sum_{k=1}^n \mu_k p_{ki} z_{ki} - \mu_i z_{ii} &= -\lambda_i(1 - p_{ii}) \\ &\quad \text{for all } i, \end{aligned} \quad (2)$$

$$\begin{aligned} \alpha_i x_j + \sum_{k=1}^n \mu_k p_{ki} z_{kj} - \mu_i z_{ij} + \alpha_j x_i \\ + \sum_{k=1}^n \mu_k p_{kj} z_{ki} - \mu_j z_{ji} &= \lambda_i p_{ij} + \lambda_j p_{ji} \\ &\quad \text{for } i < j. \end{aligned} \quad (3)$$

Although our derivation assumed $E[X_i(t)^2] < \infty$, this is true for optimal policies, so the *performance* LP

$$(\text{Perf}) \quad \min_{x, z} \quad c^T x$$

Subject to: (1), (2), (3), and $z_{ij} \geq 0$

gives a lower bound on optimal average cost without a separate stability check [10, Sections 3 and 5]. A reformulation of the dual, called the *drift* LP, will allow us to compare this bound to others, so we state it here. See Ref. 11, Appendix A for a derivation.

$$(\text{Drift}) \quad \max_{q_{ij}} \sum_{i=1}^n \lambda_i \left(q_{ii} - \sum_{j=1}^n p_{ij} q_{ij} \right)$$

$$\begin{aligned} \text{Subject to: } \sum_{i=1}^n \left(\alpha_i q_{ij} + \sum_{k=0}^n u_i \mu_i p_{ik} (q_{kj} - q_{ij}) \right) \\ \geq -c_j \quad \text{for } u \in \mathcal{A} \text{ and all } j. \end{aligned} \quad (4)$$

Here, $\{q_{ij}\}$ are the dual variables for Equations (2) and (3), with the conventions that $q_{ij} = q_{ji}$ (the lower diagonal variables can be eliminated) and $q_{i0} = q_{0i} = 0$. The results in Refs 8 and 10 are stated for the special case of a reentrant line (defined in the section titled “Queueing Network Scheduling”). In this model the drift LP is

$$(\text{Reent-Drift}) \quad \max_{q_{ij}} \sum_{i=1}^n \alpha_1 (q_{ii} - q_{i,i+1})$$

$$\begin{aligned} \text{Subject to: } \alpha_1 q_{1j} + \sum_{i=1}^n u_i \mu_i (q_{i+1,j} - q_{ij}) \\ \geq -c_j \quad \text{for } u \in \mathcal{A} \text{ and all } j. \end{aligned}$$

Reentrant flow is captured through the allowable actions $\mathcal{A}$.

Many extensions to this method involve adding constraints to the performance LP. For example, if only nonidling policies are considered then $X_j(t) = \sum_{i:\sigma(i)=\sigma(j)} u_i(t)X_j(t)$ and Equation (1) is replaced by

$$x_j - \sum_{i:\sigma(i)=\sigma(j)} z_{ij} = 0 \quad \text{for all } j \quad (5)$$

$$\sum_{i:\sigma(i)=\sigma} z_{ij} - x_j \leq 0 \quad \text{for all } j, \sigma \neq \sigma(j) \quad (6)$$

To consider a specific buffer priority policy where class j is always given priority over class i by their shared station, set $z_{ij} = 0$ [8, Section 7]. Higher-order test functions are used in Ref. 9, Section 6.1 to generate additional constraints, potentially improving the bound. For example, cubic test functions $X_i(t)X_j(t)X_k(t)$ can be used to write additional constraints that include new, triply indexed variables $E[u_i(t)X_j(t)X_k(t)]$. Another advantage of adding these variables is that the performance space considered is not limited to expected queue lengths: it can include second moments, so that variance can be bounded. Once these second moment variables are included, another extension [9, Section 6.2] is to add constraints relating the first and second moments, of the form $E[Y^2] \geq E[Y]^2$, where Y is a linear combination of the $X_i(t)$. These are quadratic constraints; however, they are equivalent to the constraint that a certain matrix be positive semidefinite and can be handled efficiently by semidefinite programming.

An LP similar to (Perf) can be used to bound the throughput λ of closed reentrant lines with N customers; [8, Section 8] and [9, Section 5.2]. Noting that $\mu_i E[u_i(t)] = \lambda$ for all classes i , Equation (1) is replaced by the constraints

$$\begin{aligned} \sum_{j=1}^n \sum_{i:\sigma(i)=\sigma(j)} z_{ij} &= N, \\ \sum_{j=1}^n z_{ij} &= N \frac{\lambda}{\mu_i} \quad \text{for all } i. \end{aligned}$$

The objective is to maximize λ .

For certain queueing networks and nonidling policies, the performance LP gives

the exact achievable region: for any point (x, u) in the feasible region, x is achieved by some nonidling policy. An elegant proof is based on the connection with conservation laws (see **Conservation Laws and Related Applications**) made in Ref. 9. The quadratic test function is replaced by 2^n “potential” functions, one for each set S of classes, of the form $[f_S^T X(t)]^2$, where the vectors f_S contain the expected remaining processing time at classes in S for each class. The stationarity equations are

$$E[\Delta [f_S^T X(t)]^2] = 0. \quad (7)$$

Instead of introducing the supplementary variables z_{ij} , use the approximation that servers serve a class in S whenever they can and that classes not in S are only served when all classes in S are empty. Then Equation (7) has the form

$$\sum_{i \in S} \lambda_i f_S(i) x_i \geq b(S), \quad (8)$$

for some $b(S)$ and all S ; see Ref. 9, Section 4.1.

Now consider a single-server network, known as *Klimov’s problem* [4]. The approximations leading to Equation (8) are exact for policies that give priority to classes in S over those not in S . As a result,

$$\sum_{i \in S} \lambda_i f_S(i) x_i = b(S), \quad (9)$$

for such policies for all S . Furthermore, Equation (9) holds for $S = \{1, \dots, n\}$ for all nonidling policies. These conditions are known as *strong conservation laws*. One consequence is that Equation (8), with equality for $S = \{1, \dots, n\}$, defines the exact achievable region for nonidling policies, with vertices corresponding to buffer priority policies [12]. It is shown in Ref. 9, Section 4.2 that, for general networks, Equation (8) is a relaxation of (Perf). Thus, (Perf) gives stronger bounds than those based on Equation (8). However, for Klimov’s problem, we can conclude that (Perf) also gives the exact achievable region. The exact achievable region for Klimov’s problem was found by Tsoucas [13] using different methods.

Another implication of the conservation law approach is that the region defined by Equation (8), with equality for $S = \{1, \dots, n\}$, is an extended polymatroid that allows the LP to be easily solved using a one-pass algorithm [14, Section 2] and optimal policies to be more simply expressed as index policies [15]. Some other networks also satisfy strong conservation laws, for example, Jackson networks [16] and networks with switching times [17,18]. Certain systems nearly satisfy conservation laws, allowing bounds to be developed as in Ref. 19. In Ref. 9, the potential function method (Eq. 8) is applied to general networks using other parameters f_S ; however, as noted above, this approach gives weaker bounds than the quadratic test functions used in (Perf).

APPROXIMATE LINEAR PROGRAMMING

Approximate linear programming (ALP) was originally proposed by Schweitzer and Seidmann [20]. It starts with the LP form of the Bellman optimality equations, then approximates the differential cost by a linear combination of a small number of functions, giving a small number of variables. For quadratic approximating functions and our queueing network, the structure of the constraints allows them to be reduced to a smaller, though still exponentially large, set. This LP is only slightly larger than the achievable region LP of the section titled “Achievable Region Method” but gives a tighter bound. Let $p_u(x, y)$ be the transition probability from state x to state y under action u . Define the dynamic programming operator

$$(T_u h)(x) = c^T x + \sum_y p_u(x, y) h(y).$$

The average cost optimality equation is

$$J + h(x) = \min_{u \in \mathcal{A}(x)} (T_u h)(x) \quad \text{for all } x. \quad (10)$$

Because Equation (10) only determines h up to an additive constant, we can set $h(0) = 0$. Due to the infinite state space, additional conditions are needed for Equation (10) to have a unique solution J^*, h^* . For networks

with linear costs, the appropriate conditions are that h is bounded below by a constant and above by a quadratic; see Ref. 21, Theorem 2.1 and Section 7. Under these conditions, $h^*(x)$ is the differential cost, that is, the expected additional cost of starting in state x compared to state 0 under the optimal policy.

Any J, h , where h is bounded above and below by a quadratic, satisfying the average cost inequality

$$J + h(x) \leq (T_u h)(x), \quad \text{for all } u \in \mathcal{A}(x) \text{ and all } x \quad (11)$$

is a lower bound, $J \leq J^*$ (see Ref. 22, Appendix A). For a discussion of when this conclusion is valid for general MDPs, see Ref. 23, Section 3 and the references therein. Maximizing over J gives J^* . Now, consider the quadratic approximation $h(x) = \frac{1}{2} x^T Q x + p x$ where Q is symmetric. Substitution into Equation (11) gives an LP in the variables J, Q, p whose solution is a lower bound on J^* . There is one constraint for each state-action pair; however, because they are linear in the index x , the constraints for each u can be reduced to the constraint at the smallest x , that is, $x = u$, and a limiting constraint at each $x_i \rightarrow \infty$. The reduced ALP is

$$\begin{aligned} (\text{ALP}) \quad & \max_{J, Q, p} J \\ \text{Subject to:} \quad & J \leq d^u \quad \text{for all } u \in \mathcal{A} \\ & c_i^u \geq 0 \quad \text{for all } i \text{ for all } u \in \mathcal{A}, \end{aligned}$$

where

$$d^u = \sum_{k=1}^n \left[u_k \left(c_k^u + \mu_k \sum_{j=0}^n p_{kj} \left(\frac{1}{2} q_{kk} + \frac{1}{2} q_{jj} - q_{kj} + p_j - p_k \right) \right) + \alpha_k \left(\frac{1}{2} q_{kk} + p_k \right) \right], \quad (12)$$

$$c_i^u = c_i + \sum_{k=1}^n \left(\alpha_k q_{ik} + \sum_{j=0}^n u_k \mu_k p_{kj} (q_{ji} - q_{ki}) \right). \quad (13)$$

For a derivation, see Ref. 22, Section 4.1 or Ref. 24, Appendix A. For the special case of a reentrant line,

$$d^u = \sum_{i=1}^n \left[u_i \left(c_i^u + \mu_i \left(\frac{1}{2} q_{ii} + \frac{1}{2} q_{i+1,i+1} - q_{i,i+1} + p_{i+1} - p_i \right) \right) \right] + \alpha_1 \left(\frac{1}{2} q_{11} + p_1 \right),$$

$$c_i^u = c_i + \alpha_1 q_{1i} + \sum_{j=1}^n u_j \mu_j (q_{i,j+1} - q_{ij}).$$

Note that the second constraint in ALP is the same as the constraints (4) in (Drift). It is shown in Ref. 11 that ALP is a stronger bound than the achievable region LP; numerical tests show that the improvement can be substantial.

Stronger ALP bounds can be obtained by adding terms to the approximation architecture for h ; however, this makes Equation (11) nonlinear in x , so that it cannot be reduced to as small a set of constraints. Piecewise quadratic functions are used in Refs 24, 25, and 22, Section 4.3. Exponential and other functions are tested numerically in Ref. 22.

For a closed reentrant line, throughput λ can be bounded using a quadratic approximation [26]. The key change is to use the cost rate $\sum_i u_i(x) \mu_i$, which has expectation λ . It is also possible to obtain a throughput bound as a function of N . Choose the form of the bound to be $\lambda(N) = \alpha' N / (N + \nu)$ and also parameterize $h(x, N) = h(x) / (N + \nu)$. Letting $N \rightarrow \infty$ gives an LP that can be solved for α' . Substituting α' into the constraints and multiplying by $N + \nu$ eliminates N , yielding a second LP that can be solved for ν . Both of these bounds are tighter than the LP bounds in Ref. 8, Section 8 and Ref. 27.

LP UPPER BOUNDS

Simulating any policy gives an upper bound on J^* . However, upper bounds on classes of policies are of interest when studying stability or sensitivity of performance to the policy. A common approach is to consider all nonidling policies, for which the (worst) performance LP is

$$(\text{UB-Perf}) \max_{x, z} c^T x$$

Subject to: (2), (3), (5), (6) and $z_{ij} \geq 0$

and its dual is

$$(\text{UB-Drift}) \min_{q_{ij}} \sum_{i=1}^n \lambda_i \left(q_{ii} - \sum_{j=1}^n p_{ij} q_{ij} \right)$$

$$\text{Subject to: } \sum_{i=1}^n \left(\alpha_i q_{ij} + \sum_{k=0}^n u_i \mu_i p_{ik} (q_{kj} - q_{ij}) \right) \leq -c_j \quad \text{for all } j \text{ such that}$$

$$\sum_{i: \sigma(i)=\sigma(j)} u_i = 1, \quad u \in \mathcal{A}.$$

Note that the constraints are indexed by actions u that are nonidling at server $\sigma(j)$ and that the dual variables associated with Equations (2) and (3) are now $-q_{ij}$. Some numerical results for these upper bounds are reported in Ref. 8, Section 7. The corresponding upper bound ALP is

$$(\text{UB-ALP}) \min_{J, Q, p} J$$

Subject to: $J \geq d^u$ for all $u \in \mathcal{A}$,

$c_i^u \leq 0$ for all i such that

$$\sum_{j: \sigma(j)=\sigma(i)} u_j = 1 \text{ for all } u \in \mathcal{A},$$

using Equations (12) and (13) for d^u and c_i^u . Once again (UB-ALP) is a stronger bound than the achievable region LP [11]. Upper bound results for some ALPs are given in Ref. 24.

PATHWISE BOUNDS

Another way to obtain a lower bound is to define a simpler system $X^*(t)$ that has at least as many service completions as the original, either on a sample path or in expectation. This section describes two bounds from Ref. 28, Section 1. Sample path methods apply to general arrival and service processes. In this section, we will allow general arrival processes but still assume that service times are independently exponentially distributed.

The roughest approximation simply ignores the competition for servers by allowing all classes to be served simultaneously using a nonidling policy, which makes it a generalized Jackson network [see **Jackson Networks (Open and Closed)**]. To obtain a sample path bound, let $S_i(t)$ be a Poisson process with rate μ_i , independent for each class i , representing the number of potential class i service completions by time t . A class i service completion occurs at time t if there is a potential service completion and $u_i(t) = 1$. In the Jackson network, a service completion occurs if there is a potential service completion and $X_i^*(t) > 0$. Also, if there is probabilistic routing, a customer is assigned the same route in both systems. Customers in the Jackson network depart each class on their route at least as soon as in the original network; in particular, they depart the network at least as soon. Hence, the Jackson network gives a pathwise lower bound on the total number of customers: $\sum_i X_i^*(t) \leq \sum_i X_i(t)$ with probability 1.

Better bounds can be constructed using the workload in the system for each station, which can only be reduced at unit rate by any policy. A variant of workload is used in Ref. 28, Section 2. Assume that routing is deterministic and that service times depend only on the station, not the class, with a Poisson process $S_\sigma(t)$ with rate μ_σ representing potential service completions for station σ . Define

$$W(t) = MX(t),$$

where $M_{\sigma,i} = 1$ if class i customers require at least one more service from station σ and 0 otherwise, that is, $W_\sigma(t)$ is the number of customers in the system at t that require at least one more service from station σ before exiting. Consider a modified system in which arrivals split into one customer for each station σ that they will visit. These customers move through a series queue (no competition for servers) until they arrive at their first class served by station σ . This station operates in isolation as a Klimov model (see **Klimov's Model**): customers skip classes in their route that are not at this station. A last-buffer-first-served (LBFS) policy is used. Consider the departure process $D_\sigma^*(t)$

of customers departing the Klimov model for station σ . The LBFS policy is optimal in the sense that it gives a pathwise upper bound on $D_\sigma^*(t)$ for any service discipline. Note that the assumption that service rates are by station is needed for LBFS to be optimal.

Now compare the corresponding departure process $D_\sigma(t)$ for the original network, that is, the number of service completions by server σ by time t that are last visits by a customer to station σ . Customers in the Klimov model arrive at least as soon as customers arrive at their first class served by that station in the original network. Because it sees earlier arrivals and skips some classes, any departure process for the original process is feasible for the Klimov model, inserting idle times as needed. Hence, the departure process for the Klimov model using the LBFS policy is also a pathwise upper bound for departures from the original network: $D_\sigma^*(t) \geq D_\sigma(t)$, or equivalently, $W^*(t) \leq W(t)$ with probability 1.

Each value of $W^*(t)$ can be converted to a minimum number of customers using the LP

$$\begin{aligned} \min \quad & \sum_{i=1}^n X_i \\ \text{Subject to:} \quad & MX \geq W^*(t) \\ & X \geq 0. \end{aligned}$$

The optimal objective function value is a pathwise lower bound on $\sum_i X_i(t)$. To obtain a lower bound on the expected number of customers, one could simulate the modified system, solving the LP each time $W^*(t)$ changed, or solving the LP parametrically for all $W^*(t)$ before simulating.

LYAPUNOV FUNCTION BOUNDS

The section titled “Achievable Region Method” used equilibrium equations for quadratic test functions. A related idea is to find a Lyapunov function that satisfies a drift condition, namely, it decreases in expectation after one transition from all large states for some class of policies. Lyapunov functions are typically used to establish stability; in Ref. 29 they are used to obtain bounds. Their bounds are explicit; however, because of the

approximations involved, they are not likely to be as tight as the bounds presented in the previous sections. If the drift parameter is known, it can be used to construct an upper bound on the tail probabilities and expectation of the Lyapunov function under the stationary distribution. The first bound uses the workload of each station as a “lower” Lyapunov function, giving lower bounds on the expected workload.

For any stationary, countable-state discrete-time Markov chain with transition probabilities $p(x, y)$, Φ is a lower Lyapunov function if $\Phi(x) \geq 0$ and, for some drift parameter $\gamma > 0$,

$$\sum_y p(x, y) \Phi(y) \geq \Phi(x) - \gamma \text{ for all } x. \quad (14)$$

Note that the inequality (14) is reversed from that of a Lyapunov function. For networks,

$$\Phi(x) = W_\sigma(x) = M_\sigma x,$$

where $M_{\sigma,i}$ is the expected time station σ serves a class i customer before it leaves the system, is a lower Lyapunov function. Here $W_\sigma(x)$ is the workload for station σ , that is, the expected time for station σ to serve all customers in the system. It satisfies Equation (14) with $\gamma = 1 - \rho_\sigma$, that is, the station can only decrease its workload at rate $1 - \rho_\sigma$. Letting $\Delta\Phi(t) = \Phi(X(t+1)) - \Phi(X(t))$, the equilibrium equation $E[\Delta\Phi(t)] = 0$ and Equation (14) impose a limit on the increase in Φ . However,

$$E[\Delta\Phi(t) | \Delta\Phi(t) > 0] P(\Delta\Phi(t) > 0) \geq p_{\min} \nu_{\min},$$

where $p_{\min}$ is the smallest probability, over all states x and actions u , that $\Phi(x)$ will increase and $\nu_{\min} > 0$ is the smallest amount by which $\Phi(x)$ can increase. For reentrant lines, $p_{\min} = \alpha_1$ and $\nu_{\min} = M_{\sigma,1}$. These relationships imply a geometric lower bound on the tail probabilities and a lower bound on the expected workload at station σ

$$E[W_\sigma(X(t))] \geq \frac{\alpha_1 \rho_\sigma^2}{4(1 - \rho_\sigma)}.$$

Extensions to more general networks are given in Ref. 29 using the concept of a virtual station. Upper bounds on the expected

number of customers are also found using piecewise linear Lyapunov functions for networks with two stations.

It is sometimes possible to construct an (upper) Lyapunov function h and J satisfying Equation (11) without solving the LP of the section titled “Approximate Linear Programming.” Under the conditions on h discussed there, J gives a lower bound on J^* .

PHASE-TYPE (PH) DISTRIBUTIONS

RAFAEL PÉREZ-OCÓN
Department of Statistics and
Operational Research,
University of Granada,
Granada, Spain

The phase-type (PH) distributions, as they are known, were introduced by Neuts [1]. They play an important role in modeling random phenomena due to their interesting properties, and they also have a widespread use in applied probability. A PH distribution is the distribution of the absorption time in a Markov chain in continuous time with a finite-state space and one absorbent state. The class of PH distributions has important closure properties which make it very versatile in application. This class is weakly dense in the class of distribution functions (CDFs) defined on the positive real half-line, which allows us to approach general distributions by elements of this class. The use of PH distributions in stochastic modeling leads to results that can be presented in algorithmic form, and consequently, the results are susceptible to computational implementation. The PH distributions and the Markovian arrival processes are the basic elements in what is known as matrix-analytic methods. The definition and properties of PH distributions and their applications in different domains of application are presented in the following sections in a condensed form.

DEFINITION AND EXAMPLES

First, some definitions of operations related to PH distributions and frequently used in the article are presented.

Exponential of a Matrix. The matrix exponential of a finite matrix A of order $n \times n$, is defined by

$$\exp(A) = \sum_{n=0}^{\infty} \frac{1}{n!} A^n.$$

Product and Sum of Kronecker. If A and B are rectangular matrices of orders $m \times n$ and $p \times q$ respectively, their Kronecker product, denoted by $A \otimes B$, is the matrix of order $mp \times nq$ defined by

$$A \otimes B = \begin{pmatrix} a_{11}B & a_{12}B & \cdots & a_{1n}B \\ a_{21}B & a_{22}B & \cdots & a_{2n}B \\ \vdots & \vdots & & \vdots \\ a_{m1}B & a_{m2}B & \cdots & a_{mn}B \end{pmatrix}.$$

In compact form it is written as $A \otimes B = [a_{ij}B]$.

If A and B are square matrices of orders m and n , respectively, their Kronecker sum, is defined as $A \oplus B = A \otimes I_n + I_m \otimes B$, where I_j indicates the identity matrix of order j .

PH Distributions. Let a continuous-time Markov chain $\{X(t), t \geq 0\}$ be with state space $S = \{1, 2, \dots, m, m+1\}$. States $1, \dots, m$ are transient and state $m+1$ is absorbent. Ordering the states appropriately, the infinitesimal generator (or simply generator), can be written as

$$Q = \begin{pmatrix} T & T^0 \\ 0 & 0 \end{pmatrix}.$$

T is a matrix of order m with negative diagonal entries and nondiagonal entries that are nonnegative. Its nondiagonal entries are the transition rates among the transient states $T^0 = -Te$ (Vector e denotes a column vector with all entries equal to 1 and of order m). The eventual absorption implies that T is nonsingular.

Let α be the initial probability vector of the Markov process on the transient states, it is a row m -vector. The CDF of the time until the absorption occurs is

$$H(t) = 1 - \alpha \exp(Tt)e, t \geq 0.$$

It is said that $H(\cdot)$ is a PH distribution with representation (α, T) of order m and it is written as $\text{PH}(\alpha, T)_m$.

The quantity α_{m+1} denotes the probability that the process initiates on the absorbent state. When it is non-null, the initial vector takes the form (α, α_{m+1}) , and the distribution function $H(\cdot)$ has an atom in the origin with mass α_{m+1} . From now on, it will be considered that $\alpha_{m+1} = 0$, what is usual in applications.

The function $H(\cdot)$ is absolutely continuous on $(0, \infty)$. The probability density function $h(t)$ is

$$H'(t) = h(t) = \alpha \exp(Tt)T^0, \quad t \geq 0,$$

the hazard rate function is

$$r(t) = \frac{\alpha \exp(Tt)T^0}{\alpha \exp(Tt)e}, \quad t \geq 0.$$

The Laplace–Stieltjes transform (LST) $\phi(s)$ is a rational function, given by

$$\phi(s) = \alpha(sI - T)^{-1}T^0, \quad \text{Re}(s) \geq 0.$$

The moment of order r is

$$\mu_r = (-1)^r r! (\alpha T^{-r} e), \quad r \geq 0.$$

The representation of a PH distribution is not unique. It is denoted minimal representation the one with minor order, which is not unique either.

Examples. The generalized Erlang distribution is a PH distribution with representation

$$\alpha = (1, 0, \dots, 0),$$

$$T = \begin{pmatrix} -\lambda_1 & \lambda_1 & 0 & \cdots & 0 \\ 0 & -\lambda_2 & \lambda_2 & \ddots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ddots & -\lambda_{m-1} \\ 0 & 0 & 0 & \cdots & -\lambda_m \end{pmatrix}.$$

The hyperexponential distribution is a PH distribution with representation

$$\alpha = (\alpha_1, \alpha_2, \dots, \alpha_m),$$

$$T = \begin{pmatrix} -\lambda_1 & 0 & 0 & \cdots & 0 \\ 0 & -\lambda_2 & 0 & \ddots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ddots & 0 \\ 0 & 0 & 0 & \cdots & -\lambda_m \end{pmatrix}.$$

PROPERTIES

The following closure properties are of interest in applications, particularly with reference to reliability. Some references related to closure properties are [2–4].

Convolution. Finite convolution of PH distributions is a PH distribution.

Suppose that $F(\cdot)$ and $G(\cdot)$ are PH distributions with representations $(\alpha, T)_m, (\beta, S)_n$ respectively. Then, the convolution of $F^*G(\cdot)$ is a PH distribution of order $m + n$ with representation (γ, L) , being $\gamma = (\alpha, 0)$ and

$$L = \begin{pmatrix} T & T^0\beta \\ 0 & S \end{pmatrix}.$$

Finite Mixture. A finite convex mixture of PH distributions is a PH distribution.

Suppose that $F_i(\cdot), 1 \leq i \leq n$, are $\text{PH}(\alpha(i), T(i))$ distributions of order m_i . Let $p_i, 1 \leq i \leq n$, be the parameters of the mixture. The mixture $p_1 F_1(\cdot) + \dots + p_n F_n(\cdot)$ is a PH distribution of order $m_1 + \dots + m_n$ with representation (δ, V) , being $\delta = (p_1 \alpha(1), \dots, p_n \alpha(n))$, and $V = \text{diag}(T(i))$.

Maximum and Minimum. The maximum and minimum of PH distributions are PH distributions.

We denote by $\otimes$ and $\oplus$ the Kronecker product and sum, respectively. Suppose two random variables X and Y with PH distributions $F(\cdot)$ and $G(\cdot)$ with representations $(\alpha, T)_m, (\beta, S)_n$ respectively. Then, $A = \min\{X, Y\}$ and $B = \max\{X, Y\}$ have the respective representations $(\gamma(1), L(1))_{mn}$ and $(\gamma(2), L(2))_{mn+m+n}$, given by

$$\gamma(1) = \alpha \otimes \beta, L(1) = T \otimes I + I \otimes S = T \oplus S,$$

$$\text{and } \gamma(2) = (\alpha \otimes \beta, 0, 0),$$

$$L(2) = \begin{pmatrix} T \oplus S & I \otimes S^0 & T^0 \otimes I \\ 0 & T & 0 \\ 0 & 0 & S \end{pmatrix}.$$

Coherent Systems. A coherent system with finite independent units following PH distributions has a lifetime that follows a PH distribution.

This result is proved in [3]. New closure properties have been established [see [5,6]].

Characterization Properties

These distributions have been characterized by means of the LST and for its closure properties.

Characterization in Terms of the Laplace–Stieltjes Transforms

A distribution is a PH distribution if and only if it has the following:

- A continuous probability density function on the positive real half-line, with a possible mass at 0.
- An LST rationale.
- LST has a unique pole of maximal real part.

This result is proved in [7], and it is a versatile modeling tool. The LST of a PH distribution is rational with this characterization property.

The class of distributions with LST rational has been characterized in [8]. They are named *matrix-exponential distributions* (ME). The analytic expression of these distributions is formally very similar to the distribution of the PH ones, but the initial vector is not a probability vector, and matrix T is not a generator. The interpretation of the phases is not valid, since there is no underlying Markovian structure. In Éltetô *et al.* [9] the coefficient of variation of the ME distributions is studied in order to be minimized.

Characterization in Terms of Closure Properties

The PH distributions are the smallest class of distributions defined on the positive real half-line which have the following properties:

- They contain the point mass at zero and all exponential distributions.
- They are closed under finite mixtures and convolutions.
- They are closed under the infinite mixture.

$$G(\cdot) = \sum_{n \geq 0} (1-p)p^n F^{*n}(\cdot), \quad \text{for } 0 \leq p \leq 1.$$

This result is proved in [4]. In Latouche and Ramaswami [10], chapters 1, 2 are dedicated to the PH distributions, and basic ideas and algorithms of the matrix-analytic theory in the discrete and continuous cases are presented

Approximation Properties

The following results related to approximating properties of PH distributions are proved in [11]: The family of PH distributions is weakly dense in the family of distributions defined on the positive real half-line. There are several families that play an important role in approximating general distributions.

- *FMER class.* Finite mixtures of Erlang distributions with the same intensity parameter.
- *(S/P) class.* Series-parallel distributions (exponential distributions in series and/or parallel).
- *ME class.* Matrix-exponential distributions.

The following relations are given among these classes: $\text{FMER} \subset \text{S/P} \subset \text{PH} \subset \text{ME}$. Consequently, all these classes are weakly dense in the family of distributions defined on the positive real half-line. A procedure for fitting PH distributions to general ones and to a data-set using the EM (expectation-maximization) algorithm is given in [12].

Results of combining fitting of moments and some other features, such as percentiles, by techniques of nonlinear optimization are in [13–15]. In Lang and Arthur [16], different techniques for approximating parameters for PH distributions are applied. In Schmickler [17] mixed Erlang distributions are used for fitting empirical distributions. A survey on

statistical estimation on PH distributions including different computational programs for fitting these distributions to a data-set and to other distribution is done in [18]. In Asmussen *et al.* [19] is presented a computational program based on the EM algorithm for fitting PH distributions. In Thümmeler *et al.* [20] an approach is presented for fitting mixtures of Erlang distributions to a data-set and constructing an algorithm of the EM type.

PH-RENEWAL PROCESSES

An interesting procedure used in applications is the construction of the renewal process associated with a PH distribution. This is a renewal process in which the interarrival times are PH distributed. Let $F(\cdot)$ be a $\text{PH}(\alpha, T)_m$ distribution with absorbent state $m+1$. Every time that the state $m+1$ is reached, the Markov process with generator Q associated with the PH distribution returns instantaneously to a transient state following vector α . Considering that every visit to the state $m+1$ is a renewal, we have a PH-renewal process with underlying distribution $F(\cdot)$. The renewals are governed by a Markov process $\{J(t), t \geq 0\}$ with generator $Q^* = T + T^0\alpha$, with m states.

The renewal density is $f(t) = \alpha \exp(Q * t)T^0, t \geq 0$.

The stationary probability vector $\pi = (\pi_1, \dots, \pi_m)$ associated with Q^* satisfies $\pi Q^* = 0, \pi e = 1$, and it is $\pi = (\alpha T^{-1}e)^{-1}(\alpha T^{-1})$.

The mean value of $F(\cdot)$ is μ , and it satisfies $\mu^{-1} = \pi T^0$.

The limiting distribution of the PH-renewal process, defined by

$$F * (x) = \frac{1}{\mu} \int_0^x [1 - F(u)] du \quad \text{for } x \geq 0,$$

is a $\text{PH}(\pi, T)$ distribution.

The expected number of renewals in $(0, t]$ is

$$\begin{aligned} EN(t) &= \frac{t}{\mu} + \frac{\sigma^2 + \mu^2}{2\mu^2} \\ &+ \frac{1}{\mu} \alpha [\Pi - \exp(Q * t)] T^{-1} e, \end{aligned}$$

where $\Pi = \text{diag}(\pi_1, \dots, \pi_m)$ and σ^2 is the variance of $F(\cdot)$.

The residual lifetime, that is, the time between a time t and the next renewal, follows a $\text{PH}(\gamma, T)$ distribution with $\gamma = \alpha \exp(Q * t)$.

Given that $\exp(Q * t) \rightarrow e\pi$ for $t \rightarrow \infty$, the density of renewal approximates to $\pi T^0 = \mu^{-1}$, the inverse of the mean of the distribution $F(\cdot)$.

In this renewal process, the number of renewals in $(0, t]$ is calculated as follows. We introduce the matrices $P(n, t) = (P_{ij}(n, t)), n \geq 0$, whose entries are

$$\begin{aligned} P_{ij}(n, t) &= P\{N(t) = j, J(t) \\ &= j | N(0) = 0, J(0) = i\}, \end{aligned}$$

for $t \geq 0, 1 \leq i \leq m, 1 \leq j \leq m$. These matrices satisfy the forward Kolmogorov equations:

$$\begin{aligned} P'(0, t) &= TP(0, t), \\ P'(n, t) &= TP(n, t) + P(n-1, t)T^0\alpha, n \geq 1, \\ P(n, 0) &= \delta_{0n}I \text{ (initial condition)}, \end{aligned}$$

with δ being the delta of Kronecker. The solution of this matrix equation system is, in general, a complex problem which implies algorithmic procedures. These previous results are established in [2], including an algorithm to calculate the matrices $P(n, t)$. This renewal process can be applied to general conditions using the approximation properties of the PH distributions.

DISCRETE PH DISTRIBUTIONS

The corresponding discrete class for these distributions is defined considering a discrete-time Markov chain $\{X_n, n = 0, 1, \dots\}$ with state space $S = \{1, 2, \dots, m, m+1\}$ and transition matrix P of the form

$$P = \begin{pmatrix} T & T^0 \\ 0 & 1 \end{pmatrix}.$$

T is a substochastic matrix of order m and $I - T$ is nonsingular. If α is the initial m -vector of the Markov chain, the probability density p_k is given by

$$p_0 = 0, \\ p_k = \alpha T^{k-1} T^0, \quad \text{for } k \geq 1.$$

As in the continuous case, it is assumed that the process is not initiated in the absorbent state.

The probability generating function is

$$P(z) = z\alpha(I - zT)^{-1}T^0$$

and the factorial moment of order k ($k = 1, 2, \dots$) is

$$d^k P(z)/dz^k|_{z=1} = k!\alpha T^{k-1}(I - T)^{-k}e.$$

The geometric distribution is the discrete analog to the exponential distribution, and the binomial negative distribution is the discrete distribution corresponding to the Erlang one.

Properties similar to the ones in the continuous case are valid for the discrete PH distributions. In [9], some closure properties are proved for the discrete case.

In the continuous case, any distribution defined on the real half-line can be approximated by a PH one, but there are distributions that are not of this class. For the discrete case, the following results establish that any discrete distribution with finite support is a PH distribution.

General Property. Any probability distribution with finite support is a discrete PH distribution [1]. The representation for any discrete distribution is constructed in [21]. We give two closure properties involving discrete and continuous PH distributions and that are of interest in applications.

Infinite Mixture. Consider the mixture

$$G(\cdot) = \sum_{k \geq 0} p_k F^{*k}(\cdot),$$

where $\{p_k\}$ is a discrete $\text{PH}(\beta, S)_n$ distribution, $F(\cdot)$ a continuous $\text{PH}(\alpha, T)_m$ distribution, and $F^{*k}(\cdot)$ denotes the k -fold convolution of $F(\cdot)$ with itself. Distribution $G(\cdot)$ is a $\text{PH}(\gamma, L)_{mn}$ distribution with

$$\gamma = \alpha \otimes \beta \text{ and } L = T \otimes I + T^0 \alpha \otimes S.$$

This result is used in queueing theory, for calculating the waiting time distribution in the model M/G/1 in stationary regime [2]. Infinite mixtures of PH-continuous distributions are not in general PH distributions.

Shock Model. Consider a device subject to shocks. Every shock can produce the failure of the device, $\bar{P}_k$ being the probability of surviving to the k th shock. If $N(t)$ is the random number of shocks in $(0, t)$, the survival function of the model is

$$\bar{H}(t) = \sum_{k=0}^{\infty} P\{N(t) = k\} \bar{P}_k, \quad t \geq 0.$$

The probability density $\{p_k\}$ of the number of shocks that can cause the device to fail is represented by

$$\bar{P}_k = \sum_{r=k+1}^{\infty} p_r.$$

This is a classic model studied in [22] under nonparametric methodology when $N(t)$ is the Poisson process. Many works were dedicated to the preservation of the reliability classes, that is, to show that $H(t)$ belonged to a continuous reliability class if $\{p_k\}$ belonged to the corresponding discrete class.

If the shocks occur according to a PH-renewal process with the underlying representation $\text{PH}(\alpha, T)_m$ distribution and it starts according to an initial probability vector η , and the probability density $\{p_k\}$ is a discrete $\text{PH}(\beta, S)_n$ distribution, then the distribution function $H(\cdot)$ is a $\text{PH}(\gamma, L)_{mn}$ with

$$\gamma = \eta \otimes \beta, L = T \otimes I + T^0 \alpha \otimes S.$$

This result is proved in [23], and it is the first time that an explicit form of the distribution function $H(\cdot)$ is determined. In a certain sense, it is a closure property for the PH distributions. Two shock models under inspections and perfect repair involving PH distributions are studied in [24]. A shock-and-wear model under policy N involving PH distributions is studied in [25].

APPLICATIONS OF PH DISTRIBUTIONS

The PH distributions are playing a central role in stochastic modeling. There are several practical reasons for using them: the Markovian structures when they are used, the closure properties, and the approximating properties.

The PH distribution are based in the exponential distribution by means of the phases, and so the no-memory property can be included in the study. But this implies that the number of states increases and the matrices are of high order. So, algorithmic procedures and computational treatment of the results are considered in applications. In Li and Cao [26] is presented a factorization method for reducing the order of the matrices.

The closure properties are very useful in modeling. In reliability systems with multiple units under repair, or in queueing systems, these properties allow operating with the same class of distributions, simplifying the calculations. The model that governs the systems is a Markov process though with vector state space, and matrices play a central role in the study. This shows that PH distributions take an essential part in the matrix-analytic methods. In Ref. 2, these methods are applied to the queue PH/PH/1, and in [27] to a reliability system with units in cold standby. In both cases, the process governing the system has the same generator, showing the versatility of the methods.

The inclusion of phases allows introduction of memory in the behavior of the systems, as in [28]. In general, the phases in the representation of a PH distribution do not have a physical significance. However, in reliability, the phases can be interpreted as different steps in a degradation [29] and/or recovery process, and also for indicating the design and control of the repair [30].

A survey with examples where these distributions are applied in different domains such as engineering, social sciences, and survival is in [31]. The PH distributions have been extensively applied in queueing theory, as in [2,8–10,32,33] and references therein. Formulas for calculating the stationary distribution in matrix-geometric form are calculated in [34]. The first paper considering

PH distributions in the study of reliability systems is [35], and from then, many papers have been published, as in [24,25,28] and references therein. They are being applied in other domains; in [36] PH distributions are applied to medical, pharmacological or societal data-sets.

The approximation of the transition functions in a semi-Markov process by PH distributions is studied in [37], but a systematic treatment of semi-Markov processes under PH distributions is not performed.

Further Properties and Extensions

PH distributions have been presented from the point of view of their applicability in constructing and solving models. Some theoretical elements completing the previous results, such as the irreducibility of the generator and a discussion about the minimal representation, are studied in [2]. In Aldous and Shepp [38], it is proved that the order of a PH distribution is at least as large as the inverse of its coefficient of variation -1 . An upper triangular representation for a particular subclass of PH distributions is constructed in [39]. Many other properties are discussed in other papers; see Refs 39–41, among others.

The extension to the multidimensional case of the univariate PH distributions has been considered in applications to reliability [40], and in systems with dependent components [41].

In Shi and Guo [42] the extension of the PH distributions to the case of infinite phases is studied; this new class is denoted by SPH, and certain approximation properties are established.

POINT AND INTERVAL AVAILABILITY

TERJE AVEN

Risk Management, and Planning,
University of Stavanger,
Stavanger, Norway

INTRODUCTION

We study a system subject to random deterioration and failure. At failures, repairs or replacements are performed, and the system resumes operation. To characterize the performance of the system, different measures can be used. In this article, we address the following two measures:

- The probability that the system is functioning at a certain point in time (point availability).
- The probability that the system is functioning during a specified interval $[u,v]$ (interval availability).

Traditionally, focus has been placed on analyzing the point availability and its limit (the steady-state availability). For a single component the steady-state formula is given by $MTTF/(MTTF + MTTR)$, where MTTF and MTTR represent the mean time to failure and the mean time to repair (mean repair time), respectively. The steady-state probability of a system comprising several components can then be calculated using the theory of complex (monotone) systems.

Compared to the limiting point availability it is of course more complicated to compute the performance measures related to a time interval. Using simplifications and approximations, it is, however, possible to establish formulae that can be used in practice.

In this article, we will look closer at the above availability measures. We establish methods and formulae for computing these

measures. We also present some asymptotic results, for large time intervals and for systems having highly available components. We first address the one-component case, then more complex systems.

Our focus are situations where the system is being repaired or replaced immediately at failures. Safety systems where the possible failures are hidden until the system is activated or tested will not be covered. We refer to Rausand and Høyland [1] for a review of availability models applicable in such cases.

Our main reference is Aven and Jensen [2], which also covers analysis of other performance measures than the availability measures, including measures related to the number of system failures. Two key references to the classical availability theory are Barlow and Proschan [3,4].

BASIC SETUP

Let X_t be the state of the system, defined by $X_t = 1$ if the system is functioning at time t and 0 otherwise. Furthermore, let T_k , $k \in \mathbb{N}$ (here $\mathbb{N} = \{1, 2, \dots\}$) represent the length of the k th operation period, and let R_k , $k \in \mathbb{N}$, represent the length of the k th repair/replacement time for the system (Fig. 1). We assume that (T_k) , $k \in \mathbb{N}$, and (R_k) , $k \in \mathbb{N}$, are independent i.i.d. sequences of positive random variables. We denote the probability distributions of T_k and R_k by F and G , respectively, and assume that they have finite means μ_F and μ_G , respectively.

In reliability engineering, μ_F and μ_G are referred to as the *mean time to failure* (MTTF) and the *mean time to repair* (MTTR), respectively.

To simplify the presentation, we also assume that F is an absolutely continuous distribution, that is, F has a density function f and failure rate function λ . We do not make the same assumption for the distribution function G , since that would exclude discrete repair time distributions that are often used in practice.

Figure 1. Time evolution of a failure and repair process for a one-component system starting at time $t = 0$ in the operating state.

In some cases, we also need the variances of F and G , denoted as σ_F^2 and σ_G^2 , respectively. In the following, when writing the variance of a random variable, it is tacitly assumed that these are finite.

The sequence $T_1, R_1, T_2, R_2, \dots$ forms an alternating renewal process. We introduce the following variables:

$$S_n = T_1 + \sum_{k=1}^{n-1} (R_k + T_{k+1}), \quad n \in \mathbb{N}$$

and

$$S_n^\circ = \sum_{k=1}^n (T_k + R_k), \quad n \in \mathbb{N}.$$

By convention, $S_0 = S_0^\circ = 0$ and sums over empty sets are zero. We see that S_n represents the n th failure time, and S_n° represents the completion time of the n th repair.

The S_n sequence generates a modified (delayed) renewal process N with renewal function M . The first interarrival time has distribution F . All other interarrival times have distribution $F * G$ (the convolution of F and G , defined by $F * G(t) = \int_0^t F(t-s) dG(s)$), with mean $\mu_F + \mu_G$. Let $H^{(n)}$ denote the distribution function of S_n . Then,

$$H^{(n)} = F * (F * G)^{(n-1)},$$

where B^{*n} denotes the n -fold convolution of a distribution B and as usual B^{*0} equals the distribution with mass of 1 at 0. Note that we have

$$M(t) = \sum_{n=1}^{\infty} H^{(n)}(t),$$

as $N_t = \sum_{n=1}^{\infty} I(S_n \leq t)$, where I is the indicator function. The S_n° sequence generates an ordinary renewal process N° with renewal function M° . The interarrival times, $T_k + R_k$,

have distribution $F * G$, with mean $\mu_F + \mu_G$. Let $H^{(n)}$ denote the distribution function of S_n . Then,

$$H^{(n)} = (F * G)^{*n}.$$

Let α_t denote the forward recurrence time at time t , that is, the time from t to the next event: $\alpha_t = S_{N_t+1} - t$ on $\{X_t = 1\}$ and $\alpha_t = S_{N_t^\circ+1}^\circ - t$ on $\{X_t = 0\}$. Hence, given that the system is up at time t , the forward recurrence time α_t equals the time to the next failure time. If the system is down at time t , the forward recurrence time equals the time to complete the repair. Let F_{α_t} and G_{α_t} denote the conditional distribution functions of α_t given that $X_t = 1$ and $X_t = 0$, respectively. Then, we have for $x \in \mathbb{R}$ (here $\mathbb{R} = (-\infty, \infty)$)

$$\begin{aligned} F_{\alpha_t}(x) &= P(\alpha_t \leq x | X_t = 1) \\ &= P(S_{N_t+1} - t \leq x | X_t = 1) \end{aligned}$$

and

$$\begin{aligned} G_{\alpha_t}(x) &= P(\alpha_t \leq x | X_t = 0) \\ &= P(S_{N_t^\circ+1}^\circ - t \leq x | X_t = 0). \end{aligned}$$

Similarly for the backward recurrence time, we define β_t, F_{β_t} , and G_{β_t} . The backward recurrence time β_t equals the age of the system if the system is up at time t and the duration of the repair if the system is down at time t , that is, $\beta_t = t - S_{N_t}^\circ$ on $\{X_t = 1\}$ and $\beta_t = t - S_{N_t}$ on $\{X_t = 0\}$.

POINT AVAILABILITY

The point availability $A(t)$, defined as $A(t) = P(X_t = 1)$, is given as

$$\begin{aligned} A(t) &= \bar{F}(t) + \int_0^t \bar{F}(t-x) dM^\circ(x) \\ &= \bar{F}(t) + \bar{F} * M^\circ(t), \end{aligned} \quad (1)$$

where $\bar{F} = 1 - F$. This follows by using a standard renewal argument. Conditioning on the duration of $T_1 + R_1$, it is not difficult to see that $A(t)$ satisfies the following equation:

$$A(t) = \bar{F}(t) + \int_0^t A(t-x) d(F * G)(x).$$

Hence, by the renewal equation (2, p. 245) Formula 1 follows. Alternatively, we may use a more direct approach, writing

$$X_t = I(T_1 > t) + \sum_{n=1}^{\infty} I(S_n^{\circ} \leq t, S_n^{\circ} + T_{n+1} > t),$$

which gives Equation (1) by taking expectations. The point unavailability $\bar{A}(t)$ is given by $\bar{A}(t) = 1 - A(t) = F(t) - \bar{F} * M^{\circ}(t)$.

Calculating the availability at a given point in time t , $A(t)$ is difficult except for a few special cases. If, for example, the lifetime and repair times are independent and they have exponential distributions, it can be shown using Markov theory [1] that the availability of the system at time t equals

$$\frac{\mu}{\lambda + \mu} + \frac{\lambda}{\lambda + \mu} e^{-(\lambda + \mu)t},$$

where λ is the failure rate and μ is the repair rate of the unit. It is assumed that the unit is functioning at time zero.

By the Key Renewal Theorem (2, p. 247), it follows that

$$\lim_{t \rightarrow \infty} A(t) = \frac{\mu_F}{\mu_F + \mu_G}. \quad (2)$$

The right-hand side of Equation (2) is called the *limiting availability* (or steady-state availability) and is for short denoted A . The *limiting unavailability* is defined as $\bar{A} = 1 - A$. Usually μ_G is small compared to μ_F , so that

$$\bar{A} \approx \frac{\mu_G}{\mu_F}.$$

If the system has an exponential lifetime distribution with failure rate λ , it can be shown that

$$\bar{A}(t) \leq \lambda \int_0^t \bar{G}(s) ds \leq \lambda \mu_G,$$

Ref. 2, p. 107.

INTERVAL AVAILABILITY

The interval availability $A[u, v]$ is defined as $A[u, v] = P(X_t = 1, \forall t \in [u, v])$. Using that $A[u, v] = A(u)P(\alpha_u > v - u | X_u = 1)$, we see that

$$A[u, v] = \bar{F}_{\alpha_u}(v - u)A(u).$$

The interval availability for the interval $[t, t + w]$, that is, the probability that the system is up at time t and the forward recurrence time at time t is greater than w is given by

$$\begin{aligned} A[t, t + w] &= P(X_t = 1, \alpha_t > w) \\ &= \bar{F}(t + w) + \int_0^t \bar{F}(t - x + w) dM^{\circ}(x). \end{aligned}$$

This is shown by noting that

$$X_t I(\alpha_t > w) = \sum_{n=0}^{\infty} I(S_n^{\circ} \leq t, S_n^{\circ} + T_{n+1} > t + w).$$

By applying the Key Renewal Theorem (2, p. 247), it follows that

$$\lim_{t \rightarrow \infty} A[t, t + w] = \frac{\int_0^w \bar{F}(x) dx}{\mu_F + \mu_G}.$$

The limit $\int_0^w \bar{F}(x) dx / (\mu_F + \mu_G)$ is the asymptotic distribution of the forward recurrence time α_t and is denoted $F_{\infty}(w)$. Similarly we define the asymptotic distribution $G_{\infty}(w)$ of the backward recurrence time β_t .

STEADY-STATE DISTRIBUTION

The asymptotic results established above provide good approximations for the performance measures related to a given point in time or an interval. Based on the asymptotic values, we can define a stationary (steady-state) process having these asymptotic values as their distributions and means. To define such a process in our case, we generalize the model analyzed above by allowing X_0 to be 0 or 1.

Thus the time evolution of the process is, as shown in Fig. 1, beginning with an uptime, or similarly starting with a downtime.

The process is characterized by the parameters $A(0)$, $F^*(t)$, $F(t)$, $G^*(t)$, $G(t)$, where $F^*(t)$ denotes the distribution of the first uptime provided the system starts in state 1 at time 0 (i.e., $X_0 = 1$) and $G^*(t)$ denotes the distribution of the first downtime provided the system starts in state 0 at time 0 (i.e., $X_0 = 0$). Now assuming that $F^*(t)$ and $G^*(t)$ are equal to the asymptotic distributions of the recurrence times, that is, $F_\infty(t)$ and $G_\infty(t)$, respectively, and $A(0) = A$, it can be shown that the process (X_t, α_t) is stationary [5]. This means that we have, for example,

$$\begin{aligned} A(t) &= A, \quad \forall t \in \mathbb{R}_+ \\ A[u, u+w] &= \frac{\int_w^\infty \bar{F}(x) dx}{\mu_F + \mu_G}, \\ \forall u, w &\in \mathbb{R}_+ = [0, \infty). \end{aligned}$$

MONOTONE SYSTEMS

Consider now a binary monotone system comprising n independent components. For each component, we define a model as in the section titled “Basic Setup,” indexed by “ i .” The uptimes and downtimes of component i are thus denoted T_{ik} and R_{ik} with distributions F_i and G_i , respectively. The lifetime distribution F_i is absolutely continuous with a failure rate function $\lambda_i(t)$. Let $\Phi : \{0, 1\}^n \rightarrow \{0, 1\}$ be the structure function of the system, which is assumed to be monotone, that is, the structure function Φ is non-decreasing in each argument, and $\Phi(\mathbf{0}) = 0$ and $\Phi(\mathbf{1}) = 1$. The possible states of the system, “functioning” and “not functioning,” are indicated by “1” and “0,” respectively, as for the components. Then $\Phi_t = \Phi(\mathbf{X}_t)$ describes the state of the system at time t , where $\mathbf{X}_t = (X_t(1), \dots, X_t(n))$.

Let p_i denote the reliability of component i , that is, $p_i = P(X_i = 1)$. Then, if the components (i.e., the X_i s) are independent, the reliability of the system, $P(\Phi = 1)$, is a function of the p_i s. This function is referred to as the *reliability function* and is denoted $h(\mathbf{p})$, where $\mathbf{p} = (p_1, p_2, \dots, p_n)$.

Point Availability

The following results show that the point availability (limiting availability) of a monotone system is equal to the reliability function h with the component reliabilities replaced by the component availabilities $A_i(t)$ (A_i).

Theorem 1. *The system availability at time t , $A(t)$, and the limiting system availability, $\lim_{t \rightarrow \infty} A(t)$, are given by*

$$A(t) = h(A_1(t), A_2(t), \dots, A_n(t)) = h(\mathbf{A}(t)), \quad (3)$$

$$\lim_{t \rightarrow \infty} A(t) = h(A_1, A_2, \dots, A_n) = h(\mathbf{A}). \quad (4)$$

Formula 3 is simply an application of the reliability function formula with $A_i(t) = P(X_t(i) = 1)$. Since the reliability function $h(\mathbf{p})$ is a linear function in each p_i and therefore a continuous function, it follows that $A(t) \rightarrow h(A_1, A_2, \dots, A_n)$ as $t \rightarrow \infty$, which proves Equation (4).

The limiting system availability can also be interpreted as the expected proportion of time the system is operating in the long run, or as the long run average availability noting that

$$\begin{aligned} \lim_{t \rightarrow \infty} E \left[\frac{1}{t} \int_0^t \Phi_s ds \right] &= \lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t A(s) ds \\ &= \lim_{t \rightarrow \infty} A(t). \end{aligned}$$

Interval Availability

In general, it is difficult to calculate the interval availability for a monotone system. Only in some special cases it is possible to obtain practical computation formulae, and in the following we look closer into some of them.

If the repair times are small compared to the lifetimes and the lifetimes are exponentially distributed with parameter λ_i , then clearly the number of failures of component i in the time interval $(u, u+w]$, $N_{u+w}(i) - N_u(i)$, is approximately Poisson distributed with parameter $\lambda_i w$. Hence the interval availability $A[0, u]$, which is equal to $P(N_u = 0)$, is approximately exponentially distributed.

If the system is a series system, and we make the same assumptions as above, it is also clear that the number of system failures in the interval $(u, u + w]$ is approximately Poisson distributed with parameter $\sum_{i=1}^n \lambda_i w$. The number of system failures in $[0, t]$, N_t , is approximately a Poisson process with intensity $\sum_{i=1}^n \lambda_i$.

If the system is highly available and the components have constant failure rates, the Poisson distribution will in fact produce good approximations also for more general systems. To motivate this, we observe that the expected number of system failures per unit of time during the interval $(u, u + w]$, $EN_{(u, u+w]}/w$, is approximately equal to the asymptotic system failure rate λ_Φ , and $N_{(u, u+w]}$ is “nearly independent” of the history of N up to u , noting that the process $\mathbf{X}$ frequently restarts itself probabilistically [i.e., $\mathbf{X}$ reenters the state $(1, 1, \dots, 1)$]. The system failure rate λ_Φ is given by

$$\lambda_\Phi = \lim_{u \rightarrow \infty} \frac{EN_u}{u} = \sum_{i=1}^n \frac{h(1_i, \mathbf{A}) - h(0_i, \mathbf{A})}{\mu_{F_i} + \mu_{G_i}}, \quad (5)$$

where $h(x_i, \cdot)$ equals the reliability of the system given that the state of component i is x_i . For a proof of the second equality of Equation (5), see Aven and Jensen [2], p. 114.

The above asymptotic result is more formally stated and proved below.

We assume that the process $\mathbf{X}$ is a regenerative process [with regenerative state $(1, 1, \dots, 1)$]. The variable S denotes the length of the first renewal cycle of the process $\mathbf{X}$, that is, the time until the process returns to state $(1, 1, \dots, 1)$. Let T_Φ denote the time to the first system failure and q the probability that a system failure occurs in a renewal cycle, that is,

$$q = P(N_S \geq 1) = P(T_\Phi < S).$$

For $q \in (0, 1)$, let P_0 and P_1 denote the conditional probability given $N_S = 0$ and $N_S \geq 1$, that is, $P_0(\cdot) = P(\cdot | N_S = 0)$ and $P_1(\cdot) = P(\cdot | N_S \geq 1)$. The corresponding expectations are denoted as E_0 and E_1 . Furthermore, let $c_{0S}^2 = [E_0 S^2 / (E_0 S)^2] - 1$ denote the squared coefficient of variation of S under P_0 .

The notation $\xrightarrow{P}$ is used for convergence in probability and $\xrightarrow{D}$ for convergence in distribution. We write $\text{Exp}(t)$ for the exponential distribution with parameter t and $N(\mu, \sigma^2)$ for the normal distribution with mean μ and variance σ^2 .

For each component i ($i \in \{1, 2, \dots, n\}$) we assume that there is a sequence of uptime and downtime distributions (F_{ij}, G_{ij}) , $j = 1, 2, \dots$.

To simplify notation, we normally omit the index j . When assuming in the following that $\mathbf{X}$ is a regenerative process, it is tacitly understood for all $j \in \mathbb{N}$. We shall formulate conditions which guarantee that αT_Φ is asymptotically exponentially distributed with parameter 1, where α is a suitable normalizing “factor” (more precisely, a normalizing sequence depending on j). Below we focus on the factor λ_Φ . Other factors are studied in Aven and Jensen [2], see the proof of Theorem 2 below and the Bibliographic notes in Ref. 2.

The basic idea of the proof of the asymptotic exponentiality of αT_Φ is as follows: If we assume that $\mathbf{X}$ is a regenerative process and the probability that a system failure occurs in a renewal cycle, that is, q , is small (converges to zero), then the time to the first system failure will be approximately equal to the sum of a number of renewal cycles having no system failures; and this number of cycles is geometrically distributed with parameter q . Now if $q \rightarrow 0$ as $j \rightarrow \infty$, the desired result follows by using Laplace transformation. The result can be formulated in general terms as shown in Lemma 1.

A result similar to Lemma 1 was first proved by Keilson [6], see also Refs 7–9. Our version of this lemma is taken from Aven and Jensen [10].

Asymptotic results similar to those presented below have been reported in many papers and books.

A survey is given by Gertsbakh [11]. See also the summary given in the books by Gnedenko and Ushakov [8], Ushakov [12], and Kovalenko *et al.* [13, 14]. Some of the earliest results go back to the works done by Keilson [6] and Solov'yev [15].

See Bibliographic notes in Aven and Jensen [2], p. 166.

Lemma 1. Let $S, S_i, i = 1, 2, \dots$, be a sequence of nonnegative i.i.d. random variables with distribution function $F(t)$ having finite mean a , $a > 0$, and finite variance, and let v be a random variable independent of (S_i) , geometrically distributed with parameter q ($0 < q \leq 1$), that is, $P(v = k) = qp^{k-1}$, $k = 1, 2, \dots$, $p = 1 - q$. Furthermore, let

$$S^* = \sum_{i=1}^{v-1} S_i.$$

Consider now a sequence F_j, q_j ($j = 1, 2, \dots$) satisfying the above conditions for each j . Then if (as $j \rightarrow \infty$)

$$q \rightarrow 0 \quad (6)$$

and

$$qc_S^2 \rightarrow 0, \quad (7)$$

where c_S^2 denotes the squared coefficient of variation of S , we have (as $j \rightarrow \infty$)

$$\frac{qS^*}{a} \xrightarrow{D} \text{Exp}(1). \quad (8)$$

Proof. Let $\tilde{S}^* = qS^*/a$. By conditioning on the value of v , it is seen that the Laplace transform of S^* , $L_{S^*}(x) = Ee^{-xS^*}$, equals $q/(1 - pL(x))$ where $L(x)$ is the Laplace transform of S_i . Let $\psi(x) = (L(x) - 1 + ax)/x$. Then,

$$L_{S^*}(x) = \frac{q}{1 - p(1 - ax + x\psi(x))}.$$

We need to show that

$$L_{\tilde{S}^*}(x) = Ee^{-(qx/a)S^*} \rightarrow \frac{1}{1+x},$$

since the convergence theorem for Laplace transforms then give the desired result. Noting that

$$Ee^{-(qx/a)S^*} = \frac{1}{1 + px - (px/a)\psi(qx/a)}.$$

we must require that

$$(x/a)\psi(qx/a) \rightarrow 0,$$

that is,

$$[L(qx/a) - 1 + qx]/q \rightarrow 0.$$

Using that $ES = a$ and the inequalities $0 \leq e^{-t} - 1 + t \leq t^2/2$, we find that

$$\begin{aligned} 0 &\leq [L(qx/a) - 1 + qx]/q \\ &= E[e^{-(qx/a)S} - 1 + (qx/a)S]/q \\ &\leq E[(qx/a)S]^2/2q \\ &= \frac{x^2}{2} \frac{q}{a^2} ES^2 \\ &= \frac{x^2}{2} q(1 + c_S^2). \end{aligned}$$

The desired conclusion (Eq. 8) follows now since $q \rightarrow 0$ and $qc_S^2 \rightarrow 0$ (Assumptions 6 and 7).

Theorem 2. Assume that $\mathbf{X}$ is a regenerative process, and that F_{ij} and G_{ij} change in such a way that the following conditions hold (as $j \rightarrow \infty$):

$$q \rightarrow 0 \quad (9)$$

$$qc_{0S}^2 \rightarrow 0 \quad (10)$$

$$\frac{qE_1S}{ES} \rightarrow 0 \quad (11)$$

$$E_1(N_S - 1) \rightarrow 0. \quad (12)$$

Then,

$$A[0, u/\lambda_\Phi] \rightarrow e^{-u}, \text{ i.e., } \lambda_\Phi T_\Phi \xrightarrow{D} \text{Exp}(1). \quad (13)$$

Proof. Using Lemma 1, we first prove that under conditions 9–11, we have

$$\frac{T_\Phi q}{E_0 S} \xrightarrow{D} \text{Exp}(1). \quad (14)$$

Let v denote the renewal cycle index associated with the time of the first system failure, T_Φ . Then it is seen that T_Φ has the same distribution as

$$\sum_{k=1}^{v-1} S_{0k} + W_v,$$

where (S_{0k}) and (W_k) are independent sequences of i.i.d. random variables with

$$P(S_{0k} \leq s) = P_0(S \leq s)$$

and

$$P(W_k \leq w) = P_1(T_\Phi \leq w).$$

Both sequences are independent of ν , which has a geometrical distribution with parameter $q = P(N_S \geq 1)$. Hence Equation (14) follows from Lemma 1 provided

$$\frac{W_\nu q}{E_0 S} \xrightarrow{P} 0. \quad (15)$$

By a standard conditional probability argument it follows that

$$ES = (1 - q)E_0 S + qE_1 S,$$

and by noting that

$$\begin{aligned} \frac{qE_1 T_\phi}{E_0 S} &= \frac{qEW}{E_0 S} \leq \frac{qE_1 S}{E_0 S} = \frac{qE_1 S(1 - q)}{ES - qE_1 S} \\ &= \frac{\frac{qE_1 S}{ES}(1 - q)}{1 - \frac{qE_1 S}{ES}} \rightarrow 0, \end{aligned} \quad (16)$$

we see that Equation (15) holds.

Next, we will show that the ratio of λ_ϕ and $q/E_0 S$ converges to 1.

Observe that

$$\lambda_\phi = \frac{EN_S}{ES} \quad (17)$$

by the Renewal Reward Theorem (Aven and Jensen [2], p. 250).

Using Equation (17), we obtain

$$\begin{aligned} \frac{\lambda_\phi}{q/E_0 S} &= \frac{\lambda_\phi}{q/ES} \frac{E_0 S}{ES} \\ &= \frac{EN_S/ES}{q/ES} \frac{E_0 S}{ES} \\ &= \frac{EN_S}{q} \frac{E_0 S}{ES}. \end{aligned}$$

Now $EN_S/q = 1 + E_1(N_S - 1) \rightarrow 1$ in view of Equation (12), and

$$\frac{E_0 S}{ES} = \frac{1 - q \frac{E_1 S}{ES}}{1 - q} \rightarrow 1$$

by Equations (9) and (11). Hence the ratio of λ_ϕ and $q/E_0 S$ converges to 1. Combining this with Equation (14), the conclusion of the theorem follows.

It is intuitively clear that if the components have constant failure rates, and the component unavailabilities converge to zero, then the conditions of Theorem 2 would hold. Below this result will be formally established. We assume, for the sake of simplicity, that no single component is in series with rest of the system. If there are one or more components in series with the rest of the system, we know that the time to failure of these components has an exact exponential distribution, and by independence, it is straightforward to establish the limiting distribution of the total system.

Define

$$\lambda = \sum_{i=1}^n \lambda_i, \quad \tilde{\mu} = \sum_{i=1}^n \tilde{\mu}_i,$$

where

$$\tilde{\mu}_i = \sup_{0 \leq t < t^*} \{E[R_{i1} - t | R_{i1} > t]\},$$

and $t^* = \sup\{t \in \mathbb{R}_+ : \bar{G}_i(t) > 0\}$. We see that $\tilde{\mu}_i$ expresses the maximum expected residual repair time of the component i . We might have $\tilde{\mu}_i = \infty$, but we shall restrict attention to the finite case in the following. If G_i has the NBUE property, then

$$\tilde{\mu}_i \leq \mu_{G_i}.$$

If the repair times are bounded by a constant c , that is, $P(R_{ik} \leq c) = 1$, then $\tilde{\mu}_i \leq c$.

Theorem 3. *Assume that the system has no components in series with rest of the system. Furthermore, assume that component i has an exponential lifetime distribution with failure rate $\lambda_i > 0$, $i = 1, 2, \dots, n$. If $d' \rightarrow 0$, where $d' = \tilde{\lambda}\tilde{\mu}$, and there exist constants c_1 and c_2 such that $\lambda_i \leq c_1 < \infty$ and $ER_i^2 \leq c_2 < \infty$ for all i , then the conditions (Eqs 9–12) of Theorem 2 are all met, and consequently the limiting result (Eq. 13) holds, that is, $\lambda_\phi T_\phi \xrightarrow{D} \text{Exp}(1)$.*

The formal proof of this theorem is lengthy and detailed, and is omitted (2, pp. 123–127). We refer to Aven and Jensen [2] for further results providing sufficient conditions for Equations 9–12 to hold.

The above results show that the time to the first system failure is approximately exponentially distributed with parameter λ_Φ . For a system comprising highly available components, it is clear that $P(\mathbf{X}_t = \mathbf{1})$ would be close to one, hence the above approximations for the interval $[0, u]$ can also be used for an interval $(t, t + u]$.

Asymptotic Normality

Now we turn to a completely different way to approximate the distribution of the time to the first system failure. Above the up and downtime distributions are assumed to change such that the system availability increases and after a time rescaling the time to failure converges to an exponential variable. Now we leave the up and downtime distribution unchanged and establish a central limit theorem as t increases to infinity.

Theorem 4. *If $\mathbf{X}$ is a regenerative process with cycle length S , $\text{Var}[S] < \infty$ and $\text{Var}[N_S] < \infty$, then as $t \rightarrow \infty$,*

$$\sqrt{t} \left(\frac{N_{u+t} - N_u}{t} - \lambda_\Phi \right) \xrightarrow{D} N(0, \gamma_\Phi^2),$$

where

$$\gamma_\Phi^2 ES = \text{Var}(N_S - \lambda_\Phi S). \quad (18)$$

Noting that the system failure rate λ_Φ is given by

$$\lambda_\Phi = \frac{EN_S}{ES}, \quad (19)$$

the result follows from the Central limit theorem for renewal reward processes (2, p. 251). From Theorem 4 we obtain an approximate normal distribution for the interval availability.

If the system failure rate is small, then we have

$$\gamma_\Phi^2 \approx \lambda_\Phi.$$

This is seen by noting that

$$\begin{aligned} \gamma_\Phi^2 &= \frac{\text{Var}(N_S - \lambda_\Phi S)}{ES} = \frac{E(N_S - \lambda_\Phi S)^2}{ES} \\ &\approx \frac{EN_S^2}{ES} \approx \frac{EN_S}{ES} = \lambda_\Phi, \end{aligned}$$

where the last approximation follows by observing that if the system failure rate is small, then N_S with a probability close to one is equal to the indicator function $I(N_S \geq 1)$. More formally, it is possible to show that under certain conditions, $\gamma_\Phi^2/\lambda_\Phi$ converges to one (2, p. 130).

From the above theorem, we establish an approximation for the interval availability:

$$A[t, t + u] \approx P(N(0, 1) \leq -\lambda_\Phi \sqrt{t}/\gamma_\Phi).$$

A STANDBY SYSTEM

In this section, we study the performance of a standby system comprising two identical components of which one is normally operating and the other is in (cold) standby. The following additional assumptions are made:

- Failed components are repaired. Only one component can be repaired at a time (one repair facility/channel), the repair policy is “first come first served.”
- Switchover to the standby component is perfect, that is, instantaneous and failure free.
- A standby component that has completed its repair is functioning at demand, that is, the failure rate is zero in the standby state.
- All failure times and repair times are independent with probability distributions $F(t)$ and $G(t)$, respectively. F is absolutely continuous and has finite mean, and G has finite third-order moment. We assume

$$\int_0^\infty F(t) dG(t) > 0.$$

In the following, T refers to a failure time of a component and R refers to a repair time.

The squared coefficient of variation of the repair time distribution is denoted c_G^2 .

Let Φ_t denote the state of the system at time t , that is, the number of components functioning at time t ($\Phi_t \in \{2, 1, 0\}$). The process Φ is a regenerative process. It is seen that the time points when Φ jumps to state 1 are regenerative points, that is, the time points when (i) the operating component fails and the second component is not under repair (the process jumps from state 2 to 1) or (ii) both the components are failed and the repair of the component being repaired is completed (the process jumps from state 0 to 1).

A cycle refers to the length between two consecutive regenerative points. We define Y and S as the system downtime in a cycle and the length of a cycle, respectively. It follows from the Renewal Reward Theorem that

$$\bar{A} = \frac{EY}{ES}. \quad (20)$$

Here, system downtime corresponds to the time where two of the components are not functioning. Let us now look closer into the problem of computing $\bar{A}$, given in Equation (20).

Using Equation (20) and that the regenerative points for the process Φ are generated by the jumps from state 2 to 1, the limiting system unavailability $\bar{A}$ can be written as

$$\bar{A} = \frac{E[\max\{R - T, 0\}]}{ET + E[\max\{R - T, 0\}]} \quad (21)$$

$$= \frac{(\mu_G - w)}{\mu_F + (\mu_G - w)}, \quad (22)$$

where

$$w = E[\min\{R, T\}] = \int_0^\infty \bar{F}(t)\bar{G}(t) dt,$$

noting that $\max\{R - T, 0\} = R - \min\{R, T\}$ and the system downtime equals zero if the repair of the failed component is completed before the failure of the operating component, and equals the difference between the repair time of the failed component and the time to failure of the operating component

if this difference is positive. Thus, we have proved the following theorem.

Theorem 5. *The unavailability $\bar{A}$ is given by Equation (22).*

We now assume an exponential failure time distribution $F(t) = 1 - e^{-\lambda t}$. Then, we have

$$\bar{A} \approx \bar{A}', \quad (23)$$

where

$$\bar{A}' = \frac{\lambda^2}{2} ER^2 = \frac{\delta^2}{2} [1 + c_G^2]. \quad (24)$$

This gives a simple approximation formula for computing $\bar{A}$. The approximation (Eq. 23) is established formally by the following proposition.

Proposition 1. *If $F(t) = 1 - e^{-\lambda t}$, then*

$$0 \leq \bar{A}' - \bar{A} \leq (\bar{A}')^2 + \frac{\delta^3}{6} \frac{ER^3}{\mu_G^3}. \quad (25)$$

Proof. Using that $1 - e^{-\lambda t} \leq \lambda t$ and changing the order of integration, it follows that

$$\begin{aligned} \bar{A} &= \frac{\lambda(\mu_G - w)}{1 + \lambda(\mu_G - w)} \leq \lambda(\mu_G - w) \quad (26) \\ &= \lambda \int_0^\infty F(t)\bar{G}(t) dt \\ &\leq \lambda \int_0^\infty (\lambda t)\bar{G}(t) dt \\ &= \lambda^2 \frac{1}{2} ER^2 = \bar{A}'. \end{aligned} \quad (27)$$

It remains to show the right-hand inequality of Equation (25). Considering

$$\begin{aligned} \bar{A}(1 + \lambda(\mu_G - w)) &= \lambda \int_0^\infty F(t)\bar{G}(t) dt \\ &\geq \lambda \int_0^\infty \left(\lambda t - \frac{1}{2}(\lambda t)^2 \right) \bar{G}(t) dt \\ &= \bar{A}' - \frac{1}{6} \lambda^3 ER^3 \end{aligned}$$

and the inequalities $\bar{A} \leq \lambda(\mu_G - w) \leq \bar{A}'$ obtained above, it is not difficult to see that

$$\begin{aligned}
0 \leq \bar{A}' - \bar{A} &\leq \bar{A}\lambda(\mu_G - w) + \frac{1}{6}\lambda^3 ER^3 \\
&\leq (\bar{A}')^2 + \frac{1}{6}\lambda^3 ER^3,
\end{aligned}$$

which completes the proof.

Hence $\bar{A}'$ overestimates the unavailability and the error term will be negligible provided that $\delta = \mu_G/\mu_F$ is sufficiently small.

FINAL REMARKS

This article covers only a small number of availability models compared to the large number of models presented in the literature, see the survey paper by Smith *et al.* [16]. Our focus has been the basic models. A large category of models not included are models addressing preventive maintenance.

This category of models is often developed with the purpose of optimizing maintenance (replacement) policies. We refer to Aven and Jensen [2], Chapter 5 and its Bibliographic notes. See also Dijkhuizen and Heijden [17].

For some recent papers on availability models, see Zhang *et al.* [18] and Montoro-Cazorla and Pérez-Ocón [19], and the references therein.

Furthermore, we have not included models where some components remain in “suspended animation” while a component is being repaired/replaced. When repair of the failed component is completed, the remaining components resume operation. At any instant, they are not “as good as new,” but rather as good as they were when the system stopped operating. Then, it can be shown that the long run (expected) proportion of time the system is functioning equals (Barlow and Proschan [4] and Aven [20])

$$\frac{1}{1 + \sum_{i=1}^n \frac{\text{MTTR}_i}{\text{MTTF}_i}}. \quad (28)$$

This expression is to be compared to

$$h(\mathbf{A}) = \prod_{i=1}^n \frac{\text{MTTF}_i}{\text{MTTF}_i + \text{MTTR}_i}.$$

If the component availabilities are high, then

$$h(\mathbf{A}) \approx 1 - \sum_{i=1}^n \bar{A}_i,$$

which is seen to be approximately equal to Equation (28).

Markov models are often used for availability analysis [21]. Markov models are used to describe and analyze the movement of the system among various states, from the perfect functioning state to the complete failure state. Markov models are particularly suitable for analyzing smaller systems with complicated maintenance policies and possible dependencies between components. On the other hand, the computational problems can be significant and the assumption of exponential distributions may seem to restrict applicability. However, the so-called phase-type approach can open for other distributions. The phase-type approach makes use of the fact that a distribution function can be approximated by a mixture of Erlang distributions (with the same scale parameter), see, for example, Asmussen [22] and Tijms [23].

Markov models is a type of multistate systems, and many of the availability results obtained for the binary case have been extended to such systems (2, p. 151). See also Zio *et al.* [24] and the references therein. Finally, we would like to draw attention to semi-Markov models for availability analysis of multistate systems and we refer the readers to Csenki [25] and Limnios and Oprisan [26].

Acknowledgments

The author is grateful to an anonymous reviewer for useful comments and suggestions to an earlier version of the manuscript.

POISSON PROCESS AND ITS GENERALIZATIONS

VAIDYANATHAN RAMASWAMI
AT&T Labs Research,
Florham Park, New Jersey

A point process is a random scattering of points over a subset of the n -dimensional Euclidean space R^n , $n \geq 1$ [1]. Mathematically, it is a function $N(\cdot)$, which provides for each Borel set B , the number of points $N(B)$ falling in it. When dealing with a point process on $[0, \infty)$, it is customary to denote $N(0, t]$ by $N(t)$ and to refer to $\{N(t) : t \geq 0\}$ as the point process. Point processes arise naturally in the study of random events over time, space, or space-time and find applications in numerous areas.

Among point processes, the Poisson process [1–3] is the simplest. Yet, it is the archetype of substantially large classes of point processes through generalization in various directions.

STATIONARY POISSON PROCESS ON $[0, \infty)$

The stationary Poisson process on $[0, \infty)$ was introduced independently by Erlang [4] in 1909 as a model for call arrivals to a telephone trunking system and by Bateman [5] in 1910 as a model for α -particle emissions in a nuclear experiment. The name Poisson process, however, may have come to pass since the number of counts in any interval of length t in such a process has a distribution discovered by Siméon-Denis Poisson [6], bearing his name, and characterized by the density $p_n(t) = e^{-\lambda t} (\lambda t)^n / n!$, $n = 0, 1, 2, \dots$ for some constant $\lambda > 0$.

Poisson distribution arises as a limit of the simple binomial distribution, the distribution of the count of an event with probability p in a set of n independent repetitions of the experiment. Indeed, the conditions ($n \rightarrow \infty, p \rightarrow 0, np \equiv \lambda$) of the limit theorem render the Poisson distribution a natural

candidate for counts of rare events, a fact confirmed by many data sets including the famous example provided by Von Bortkiewicz [7,8] of the number of fatalities due to horse kicks in the Prussian army; see Feller [9] for many others.

Definition 1. The stationary Poisson process on $[0, \infty)$ is a stochastic process $N(\cdot)$ such that for any set of intervals $(a_i, b_i]$, $i = 1, \dots, k$ which are nonoverlapping and for all integers $n_i \geq 0$, we have

$$P[N(a_i, b_i] = n_i, i = 1, \dots, k] \\ = \prod_{i=1}^k e^{-\lambda(b_i - a_i)} \frac{[\lambda(b_i - a_i)]^{n_i}}{n_i!}, \quad (1)$$

where $\lambda > 0$ is a constant called the *intensity* of the process.

This definition adapted from Ref. 1 and given in terms of the probability law of $N(\cdot)$, is one that is easy to generalize to higher dimensions. However, since the specification of the probability law does not by itself guarantee any regularity properties for sample paths often required in analysis, some authors, for example Çinlar [2], prefer to define the Poisson process directly in terms of its sample path properties.

Definition 2. A stochastic process $\{N(t) : t \geq 0\}$ of counts defined on a probability space $(\Omega, \mathcal{F}, P)$ is a stationary Poisson process if (a) for almost all ω , its paths $N_\omega(\cdot)$ are right continuous with finite left limits at all points t ; (b) for almost all ω , $N_\omega(t+) - N_\omega(t-) \leq 1$ (jumps are simple, i.e., of size 1); (c) for any $t, s \geq 0$, $[N(t+s) - N(t)]$ is independent of the history $\{N(u) : u \leq t\}$ (i.e., the process has independent increments); and (d) for any $s, t \geq 0$, the distribution of $N(t+s) - N(t)$ is independent of t (i.e., increments are stationary).

In the language of Palm [10], (c) and (d) above constitute an assumption of “no after-effects.”

Characterizations of the Stationary Poisson Process

It is clear from Equation (1) that the count $N(B)$ in any set B that can be expressed as the union of a finite number of finite intervals has Poisson distribution with parameter $\lambda l(B)$, where $l(\cdot)$ is the Lebesgue measure assigning to each interval its length as its measure. This is a characterizing property of the Poisson process [11].

Theorem 1. *A stationary point process with $N(I) < \infty$ a.s. for all intervals I of finite length is a Poisson process iff there exists a $\lambda > 0$ such that, for each set B that can be expressed as the union of a finite number of finite intervals, $N(B)$ obeys the Poisson distribution with parameter $\lambda l(B)$.*

The striking feature of this theorem is that independence of the increments comes as a consequence of its simple assumptions. We do hasten to note, however, that the theorem does not hold if one attempts to weaken the assumption concerning the range of the sets B to a smaller class like the set of intervals (relevant counterexamples and references in Ref. 1, p. 30).

Theorem 2. *For the stationary Poisson process $\{N(t) : t \geq 0\}$ with intensity λ , as $\Delta t \downarrow 0$,*

$$P[N(t + \Delta t) - N(t) = 1] = \lambda \Delta t + o(\Delta t), \quad (2)$$

$$P[N(t + \Delta t) - N(t) \geq 2] = o(\Delta t). \quad (3)$$

See Çinlar [2] for a proof. Equation (2) justifies calling λ the intensity of the process; it is the expected rate at which an increment occurs in a small interval of time. Equation (3) is a condition called *orderliness* by Khinchin [12] and is the analytic analogue of the unit jump condition for sample paths. The notion of orderliness helps to obtain the following result of Renyi [11] that weakens the above condition to the probabilities of a zero count.

Theorem 3. *$N(\cdot)$, an orderly point process on $[0, \infty)$, is a stationary Poisson process iff there exists a $\lambda > 0$ such that $P(N(B) = 0) =$*

$\exp(-\lambda l(B))$ for all sets B that can be expressed as a union of a finite number of finite intervals.

Indeed, under mild conditions, the avoidance function $P[N(B) = 0]$ characterizes the law of a point process in general spaces ([1], Section 7.3). A special case of that extends Theorem 3 to Poisson processes over R^n .

For the Poisson process, it is clear that

$$E[N(t + s) - N(t) | N(u), 0 \leq u \leq t] = \lambda s, \quad \text{for all } t, s \geq 0. \quad (4)$$

The following theorem of Watanabe [13] provides one of the simplest qualitative characterizations of the Poisson process in terms of this result.

Theorem 4. *The point process $\{N(t) : t \geq 0\}$ is a stationary Poisson process with intensity λ if and only if for almost all ω , each jump of $N_\omega(\cdot)$ is of unit magnitude and Equation (4) holds.*

Poisson Process as a Markov Chain

The memory-less property embodied in condition (c) of Definition 2, and Equations (2) and (3) lead to the following.

Theorem 5. *For the Poisson process with intensity λ , $\{N(t) : t \geq 0\}$ is Markov with infinitesimal generator Q with elements*

$$Q(i, j) = \begin{cases} -\lambda & \text{if } j = i, \\ \lambda & \text{if } j = i + 1, \\ 0 & \text{otherwise.} \end{cases} \quad (5)$$

The Markov property of the Poisson process makes conditioning arguments easy in the models in which it is used; see Ref. 14, Example 2.1.2, for an example. Also, in such models one is often able to unearth embedded processes [15] that are Markovian even if the original model is not. This considerable ease of analysis accounts for the extensive use of the Poisson process in the literature on queues, inventories, dams, storage processes, insurance risk, etc. [16–18].

Inter-Event Times in a Poisson Process

Let $0 < \tau_1 < \tau_2 < \dots$ denote the successive epochs of jumps of the stationary Poisson process with rate λ , and let $X_i = \tau_i - \tau_{i-1}$, with $\tau_0 = 0$.

Theorem 6. *The inter-event times $X_1, X_2, \dots$ are independent and identically distributed with the exponential density $f(x) = \lambda e^{-\lambda x}$, $x > 0$.*

The exponential distribution has the memory-less property, namely,

$$P[X > t + s | X > s] = P[X > t].$$

For the Poisson process, this is explained by the fact that the elapsed inter-event time (which is a part of the history of the process) does not provide any information on the future waiting time for the event to occur.

An interesting set of intervals for the Poisson process comprises F_t the forward recurrence time (time to the next event after time t) and the elapsed time E_t (time since the last event before t). The Markov property of the Poisson process entails that just as any inter-event time, F_t is also exponentially distributed with parameter λ . Note, however, that $E_t \leq t$. By using a simple renewal argument, one can easily show that E_t has a point mass $e^{-\lambda t}$ at t and a density $\lambda e^{-\lambda u}$, $0 < u < t$. As $t \rightarrow \infty$, the elapsed time density also converges to the exponential distribution. Thus, the stationary forward recurrence time and stationary elapsed time for the Poisson process are both exponentially distributed with parameter λ . Indeed, among simple point processes, only the stationary Poisson process has this property.

The above facts demonstrate an interesting paradox called the *waiting time paradox* [9]. The inter-event interval containing a given epoch t , being the sum of the forward and elapsed times at t , has a mean larger than that of an inter-event time. This paradox underlying the oft-expressed despair, “Why does the bus I am waiting for always come late?” is resolved by noting that for a fixed t , a larger inter-event interval

has a higher chance of covering t compared to a shorter interval, implying that the choice of the interval covering t is inherently length-biased. This simple fact is indeed an example both of the novelty brought by probabilistic thinking as well as of how deceptive the simplicity of the Poisson process can be.

Conditional Distributions

It is straightforward [1,2] to show that for a stationary Poisson process, given that exactly n points occur in $[0, t]$ the location of those points $\tau_1 < \tau_2 < \dots < \tau_n$ in $[0, t]$ are distributed as an ordered independent sample of size n from the uniform distribution over $[0, t]$. The memory-less property and constant intensity imply that no epoch is favored over another.

The PASTA Property

In considering stationary distributions (i.e., distributions as time $t \rightarrow \infty$) of stochastic processes, one must differentiate between limits taken at an arbitrary time (i.e., as t goes to ∞ in the usual sense) or via selected subsets of epochs. As an example, in a queueing model, one may consider $X(t)$, the virtual waiting time (the waiting time as seen at an arbitrary t), or consider $X(\tau_k)$ where τ_k is the epoch of the k th arrival, and their stationary versions when they exist. These stationary distributions have ergodic interpretations respectively as the a.s. limits of the long run sample averages $\lim_{t \rightarrow \infty} t^{-1} \int_0^t X(t) dt$ taken over all time points and as long run sample averages $\lim_{N \rightarrow \infty} N^{-1} \sum_{k=1}^N X(\tau_k)$ taken over the selected set of time points $\{\tau_k\}$ only. PASTA (Poisson arrivals see time averages) [19] asserts, under general conditions, that these averages are equal when the selected epochs form a Poisson process. The conditions comprise of a nonanticipating attribute namely, that the next epoch of the observing Poisson process should be independent of the history of the observed process. The PASTA result when it holds is helpful in analysis, simulations, and statistical estimation from samples. For details, interested readers may refer to Ref. 19.

NONSTATIONARY POISSON PROCESS ON $[0, \infty)$

Generalization to the nonstationary simple Poisson process is obtained by relaxing the condition of constant intensity and assuming instead that $E[N(t)] = \Lambda(t)$, where $\Lambda(t) = \int_0^t \lambda(u) du$, where $\lambda(\cdot)$ is a nonnegative function called the *time-dependent intensity* of the process.

Definition 3. A simple nonstationary Poisson process on $[0, \infty)$ is a stochastic process $N(\cdot)$ such that for any set of intervals $(a_i, b_i]$, $i = 1, \dots, k$ which are nonoverlapping (i.e., no two of which have a common subinterval) and for any set of integers $n_i \geq 0$, we have

$$P[N(a_i, b_i] = n_i, i = 1, \dots, k] = \prod_{i=1}^k e^{-[\Lambda(b_i) - \Lambda(a_i)]} \frac{[\Lambda(b_i) - \Lambda(a_i)]^{n_i}}{n_i!}, \quad (6)$$

where $\Lambda(t) = \int_0^t \lambda(u) du$ and $\lambda(\cdot)$ is a nonnegative function on $[0, \infty)$.

One may also define a nonstationary Poisson process as in Definition 2 by replacing (d) there with the condition $E[N(t)] = \Lambda(t)$.

Assume $\lambda(\cdot)$ is continuous, and define a time change

$$u(t) = \inf\{s : \Lambda(s) > t\}, \quad t \geq 0.$$

Then $M(t) = N(u(t))$ is a stationary Poisson process with unit intensity. This artifice helps obtain results for the nonstationary Poisson process from those governing the stationary case; see Ref. 2, Chapter 4, for some examples.

Compound Poisson Process

Suppose that in Definition 2, we replace (b) by the condition that each jump can be of a random size $k \geq 1$ with probability p_k , where $\sum_1^\infty p_k = 1$, independently of the history of the process. Then, the resulting process is called a compound Poisson process. Such processes are useful in modeling batch arrivals of customers to a queue, of demands of random sizes to an inventory system, and so on. Many applied models with compound Poisson

processes lend themselves to an easy analysis with explicit formulae solutions as well; see examples and details in Ref. 2.

Martingales and Stochastic Integration

In the theory of stochastic integration [20] due to Itô—see Steele [21] for a nice summary—one considers processes defined through integrals of the type $I(t) = \int_0^t f(t) dB(t)$ where $B(\cdot)$ is a Brownian motion and f is a suitably restricted function such that $f(t)$ is measurable with respect to the history $\{B(u) : u \leq t\}$. A discussion of Itô integration is beyond our scope, but it suffices to note that this is not the same as the Stieltjes integral in classical analysis, and that it has become an important tool. A simple example of an Itô process is the value process of a portfolio wherein $f(t)$ denotes the size of the holding at time t of an asset and $B(\cdot)$ represents the price process. The standard Brownian motion $B(\cdot)$ is a martingale, and a famous result called *Girsanov's Theorem* asserts that a Brownian motion with drift can be turned into a martingale by a change of measure. These enable the construction and study of Itô integrals via the theory of martingales.

In many ways, the nonstationary Poisson process on the line is a discrete analogue of Brownian motion with drift. The Itô integral here is the sum $I(t) = \sum_{\tau_k \leq t} f(\tau_k)$ where τ_k are the event times of a Poisson process $N(\cdot)$, and f is a function whose value at t is determined by the history $\{N(u) : u \leq t\}$. A connection of the Poisson process to a closely related martingale and the development of a discrete version of the stochastic integral paralleling the continuous case can be made [22]. That development has placed the Poisson process in yet another favorable light as a tool in stochastic integration. In addition to unifying the continuous and discrete state space development of the stochastic integral, the accompanying techniques have provided powerful tools for analyzing processes with jumps and for proving many results in very general settings (details in Brémaud [22]).

Closure Properties

The set of Poisson processes is closed under independent superpositions, a fact useful in

many contexts like networks of queues where streams are merged. Thus, if N_1 and N_2 are independent Poisson processes, so is $N_1 + N_2$. The set is also closed under independent Bernoulli thinning, a result useful in networks with probabilistic routing. Thus, if each of the points of a Poisson process $N(\cdot)$ with intensity λ is independently kept or discarded with respective probabilities p and $1 - p$, the kept and discarded epochs form independent Poisson processes with respective intensities λp and $\lambda(1 - p)$. For substantial generalizations of this thinning result, see Ref. 23. Also, if the superposition of two renewal processes is Poisson, then each must be Poisson. For these and related characterizations, refer to Ref. 1.

SPATIAL POISSON PROCESS

Spatial point processes have become of increasing interest in operations research, particularly in the context of characterizing traffic and performance in wireless networks. The basic ideas parallel those of the line process. We assume as given a boundedly finite (i.e., finite on bounded sets) parameter measure $\Lambda(\cdot)$ which is a measure on the Borel sets of the underlying space $\mathcal{X}$ assumed to be a complete, separable, metric space (c.s.m.s.).

Definition 4. A stochastic process $N(\cdot)$ which assigns a (random) count of points to each Borel set B of $\mathcal{X}$ is a spatial Poisson process over $\mathcal{X}$ with parameter measure $\Lambda(\cdot)$ iff for all finite collections of bounded, disjoint Borel sets B_i and nonnegative integers n_i , we have

$$\begin{aligned} P[N(B_i) = n_i, i = 1, \dots, k] \\ = \prod_{i=1}^k e^{-\Lambda(B_i)} \frac{(\Lambda(B_i))^{n_i}}{n_i!}. \end{aligned} \quad (7)$$

If $\Lambda(B) = \int_B \lambda(x) dx$ for all B for a nonnegative, continuous function λ , the analysis is routine, but when that is not the case, technical complexities can arise; herein lies the non-triviality of the extension ([1], Section 2.4).

For $\epsilon > 0$, denote by $S_{\epsilon, x}$ the open sphere with center x and radius ϵ . The Poisson process on $\mathcal{X}$ is said to be orderly iff for all $x \in \mathcal{X}$,

$$P[N(S_{\epsilon, x}) > 1] = o(P[N(S_{\epsilon, x}) > 0]), \quad \epsilon \rightarrow 0.$$

One can show that the Poisson process is orderly iff its parameter measure $\Lambda(\cdot)$ has no atoms.

One can show in general that if a point process is such that for all bounded Borel sets, $N(B)$ has a Poisson distribution with parameter $\Lambda(B)$ for some boundedly finite measure $\Lambda(\cdot)$, then the process is Poisson. Also, an orderly process is Poisson iff we have $P[N(B) = 0] \equiv \exp[-\Lambda(B)]$ for some nonatomic boundedly finite measure Λ . These results are natural generalizations of similar results we stated for the Poisson process on the line. Closure properties under independent superposition and Bernoulli thinning also hold for spatial Poisson processes (details in Ref. 1).

Spatial Poisson processes are well studied from the point of view of characterization, computation, simulation, and statistical inference. For a detailed discussion, we refer the reader to Daley and Vere-Jones [1], Illian *et al.* [24], and Cressie [25].

A Useful Construction

We can construct a spatial Poisson process from a stationary Poisson process on the line using a time change and a random rotation.

Theorem 7. Let $\{T_n\}$ denote the successive epochs of a stationary Poisson process on $[0, \infty)$ with intensity λ . Then the set of points with radial coordinates $(\sqrt{T_n/\pi}, \Theta_n)$, where $\{\Theta_n\}$ is a sequence of i.i.d. $U(0, 2\pi)$ variables constitutes a stationary Poisson pattern on the plane with intensity λ .

Similar ideas have been used by Isham [26] on renewal processes to generate interesting planar point processes. Later, Latouche and Ramaswami [27] developed a new class called *spatial phase-type point patterns* by starting with a Markovian arrival process (MAP, see section titled, “Batch Markovian Arrival Process”) on $[0, \infty)$, general time changes, and general scattering rules. In addition to being algorithmically tractable, such processes can model a variety of spatial clusters and do not suffer from

the major restrictions of spatial homogeneity and independence of the stationary Poisson. For these reasons, they can be of use in areas like wireless and mobile communications where such assumptions are often untenable. A detailed study of the isometric case may be found in the dissertation [28] and subsequent publications of Remiche who has used the models to demonstrate the impact of spatial dependence of call arrivals on the performance of directional antennae in wireless communications.

A Limit Theorem for Superpositions

We noted that the Poisson distribution is a natural candidate for rare events. So is the spatial Poisson process in that under certain technical conditions, the superposition of a set of independent “sparse” point processes converges to a Poisson process. In many practical instances, this limit result forms an unstated justification for using a Poisson process. Note that the telephone calls to a large switch form the superposition of a large number of sparse processes of calls generated by individual users; this may give a mathematical explanation for Erlang’s success with the Poisson model for call arrivals. Due to its importance in applications, we shall state the superposition theorem carefully below. For proof, refer to Ref. 1, Chapter 9.

First, we provide a definition of sparsity.

Definition 5. A sequence of point processes $N_{ni}, n, i = 1, 2, \dots$ defined on a c.s.m.s. $\mathcal{X}$ will be called uniformly asymptotically negligible (u.a.n.) if for all bounded Borel sets $B \subset \mathcal{X}$, we have

$$\lim_{n \rightarrow \infty} \sup_i P[N_{ni}(B) > 0] = 0.$$

In addition to the above, call the set of processes an independent array if for each n , the processes $\{N_{ni} : i = 1, 2, \dots\}$ are mutually independent.

Theorem 8. Let N_{ni} denote a u.a.n. independent array of point processes on a c.s.m.s. $\mathcal{X}$, and let $N_n = \sum_{i=1}^{m_n} N_{ni}$ where m_n is a sequence of positive integers going to ∞ as

$n \rightarrow \infty$. As $n \rightarrow \infty$, N_n converges weakly to a Poisson process on $\mathcal{X}$ with parameter measure $\Lambda(\cdot)$ iff for all bounded Borel sets B with $\Lambda(\delta B) = 0$, as $n \rightarrow \infty$,

$$\sum_{i=1}^{m_n} P[N_{ni} \geq 2] \rightarrow 0 \text{ and} \\ \sum_{i=1}^{m_n} P[N_{ni}(B) \geq 1] \rightarrow \Lambda(B).$$

Weak convergence here is in the sense of stochastic process convergence; see Whitt [29] for applicable definitions.

DOUBLY STOCHASTIC POISSON PROCESS

Assume that there exists a positive random variable Λ , and that given $\Lambda = \lambda$, the random variable X has a Poisson distribution with parameter λ . The (unconditional) distribution of X is called a *doubly Poisson* or *mixed Poisson distribution*. The earliest instance of such a model is due to Greenwood and Yule [30] who considered the number of accidents to be Poisson with a parameter called *accident intensity* that varies across a worker pool and may therefore be considered random. The mixed Poisson distribution is widely used in Bayesian statistics and forms the basis of a commonly used technique called *Poisson Regression* [31] and many of its variants.

Just like the parameter of a single Poisson random variable, in a variety of applications, it may be appropriate to consider the intensity $\Lambda(\cdot)$ of a Poisson process to be random. What results is the doubly stochastic Poisson process. Thus, one assumes a stochastic process $\Lambda(\cdot)$ such that given a realization of $\lambda(\cdot)$ thereof, $N(\cdot)$ is a Poisson process with intensity function given by the sample path $\lambda(\cdot)$. As an example, we could consider the number N_t of interrupts in $(0, t]$ in a computer system to be a Poisson process for which the intensity at time t is $M_t \lambda$, where M_t , the number of jobs multitasking at time t , itself evolves as a stochastic process.

The doubly stochastic Poisson process was introduced by Cox [32] and also goes by the name Cox process. A rigorous treatment

is usually made in the context of random measures [1,33]. Cox processes find considerable use in time series analysis and Bayesian methods for them. For some interesting applications in credit modeling, refer to Lando [34] and Schönbucher [35]. Thus, the Cox process does find applications in many contexts. However, when used in their full generality in queueing models and the like, one finds that the models become quite hard to analyze; only some bounds for performance measures could be obtained and that too for certain special models [36]. However, for Cox processes on the line with an additional Markovian structure on the intensity process, much can be accomplished. That leads us to our next set of processes which can also be considered as special instances of a Cox process with batch events.

BATCH MARKOVIAN ARRIVAL PROCESS

The MAP and the Batch Markovian Arrival Process (BMAP) are generalizations obtained by assuming that the counting process combined with an auxiliary Markov process is a bivariate Markov process. The motivation for them is the fact that Markov property aids analysis of complex models by simplifying conditioning arguments [37,38].

Definition 6. A counting process $\{N_t\}$ giving the number of events in the interval $(0, t]$ is called a BMAP with parameter set $\{D_k : k = 0, 1, \dots\}$ where each D_k is an $m \times m$ matrix iff (a) there exists a continuous-time Markov chain $\{J_t\}$, called the Markov chain of phases, with infinitesimal generator $D = \sum_{k=0}^{\infty} D_k$; (b) the bivariate process $\{(N_t, J_t) : t \geq 0\}$ is Markov, and (c) after grouping the state space into sets called levels where level $L_k = \{(k, 1), \dots, (k, m)\}$, $k = 0, 1, \dots$, the infinitesimal generator matrix Q of the bivariate Markov chain has the block partitioned form

$$Q = \begin{bmatrix} D_0 & D_1 & D_2 & \cdots & \cdots \\ 0 & D_0 & D_1 & \cdots & \cdots \\ 0 & 0 & D_0 & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots \end{bmatrix}. \quad (8)$$

When $D_k = 0$ for all $k \geq 2$, the process is simply called an MAP.

It is customary to assume that D is irreducible (no redundant phases) and that D_0 is nonsingular ($N(\infty) = \infty$) [39]. However, for those instances where we need a terminating MAP or BMAP, we could assume that one of the m phases, say m , is absorbing and that no events occur once m is reached; that is, $D_n(m, j) = 0$ for all n, j .

The BMAP was introduced by Neuts [40] and was called the *Neuts process* by Ramaswami [39] who provided a detailed steady state analysis of the single server queue with BMAP input along with a substantial matrix generalization of the Pollaczek–Khinchin formula [16] for the virtual waiting time distribution. The notation used by Neuts [40] and Ramaswami [39] is different from that given here which is based on Lucantoni [41] comprising results from Ref. 39 translated into the new notation. A subsequent work by Lucantoni *et al.* [42] contains a detailed time-dependent analysis of the BMAP/G/1 queue and serves as an excellent demonstration of the tractability of BMAP. The BMAP can also be used as a model for a service mechanism with batch services [43]. A simple introduction to the BMAP can be found in Ref. 14, Chapter 3.

The inter-event times in the MAP (and BMAP) are in general correlated phase-type random variables. Indeed, the extreme generality of the BMAP follows from Schassberger [44] and Asmussen and Koole [45] who show that the MAPs form a dense subset of the set of all simple point processes on $[0, \infty)$. Models involving the BMAP and various special cases continue to be an active area of research.

POLYNOMIAL TIME PRIMAL INTEGER PROGRAMMING VIA GRAVER BASES

SHMUEL ONN

Technion, Israel Institute of Technology,
Haifa, Israel

INTRODUCTION

Linear integer programming is the following optimization problem,

$$\min \{wx : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\}, \quad (1)$$

where $w \in \mathbb{Z}^n$ is a cost, A is an integer $m \times n$ matrix, $b \in \mathbb{Z}^m$ is a right-hand side, and $l, u \in \mathbb{Z}_\infty^n$ are lower and upper bounds, with $\mathbb{Z}_\infty := \mathbb{Z} \cup \{\pm\infty\}$. It is one of the most fundamental discrete optimization problems and has a very broad modeling power and numerous applications in a variety of areas. A comprehensive treatment of the classical theory of linear integer programming is in the excellent book by Schrijver [1].

Integer programming is generally NP-hard and hence presumably intractable, but polynomial time solvable in two fundamental situations: first, when the underlying matrix is totally unimodular [2]; and second, when the number of variables is fixed [3]. The goal of this article is to describe the recent exciting developments in so-called *primal methods* for integer programming which, in particular, lead to the polynomial time solution of new broad classes of integer programming problems with linear, and more generally, various nonlinear, objective functions of the form

$$\min \{f(x) : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\}. \quad (2)$$

Our emphasis is on primal methods that lead to polynomial time solution. For other primal strategies for integer programming, see Refs 4 and 5 and the references therein.

To simplify the presentation, and since the feasible set in most of the applications is finite or can be made finite by more careful modeling, whenever an algorithm detects that the feasible set is infinite, it simply stops. So, throughout our discussion, an algorithm is said to *solve a (nonlinear) integer programming problem* if it either finds an optimal solution x or concludes that the feasible set is infinite or empty.

The function f involved in a nonlinear integer program (2) is presented either by a mere comparison oracle that, queried on two vectors x, y , answers whether or not $f(x) \leq f(y)$, or by an evaluation oracle that, queried on vector x , returns $f(x)$.

In the following section, we define Graver bases and show that they can be used to design primal algorithms for solving (non)linear integer programs in polynomial time. In the section titled “ n -Fold Integer Programming,” we consider the universal class of n -fold integer programming problems which, using the results of the following section, can be solved in polynomial time. In the section titled “Some Applications,” we describe some applications to multi-index and multicommodity transportation.

GRAVER BASED PRIMAL INTEGER PROGRAMMING

The *Graver basis* is a fundamental object in the theory of integer programming which was introduced by Graver, already back in 1975 [6]. However, only recently, in the series of articles [7–9], it was established that the Graver basis can be used to solve linear, as well as various nonlinear, integer programming problems in polynomial time. We proceed to describe these important new developments.

The *lattice* of an integer $m \times n$ matrix A is the set $\mathcal{L}(A) := \{x \in \mathbb{Z}^n : Ax = 0\}$. Let $\mathcal{L}^*(A) := \{x \in \mathbb{Z}^n : Ax = 0, x \neq 0\}$. Define a partial order $\sqsubseteq$ on $\mathbb{R}^n$ as follows: for two vectors $x, y \in \mathbb{R}^n$ put $x \sqsubseteq y$ and say that x

is *conformal* to y if for $i = 1, \dots, n$, we have $x_i y_i \geq 0$ (so x and y lie in the same orthant of $\mathbb{R}^n$) and $|x_i| \leq |y_i|$. The classical lemma of Gordan [10] implies that every subset of $\mathbb{Z}^n$ has finitely many $\sqsubseteq$ -minimal elements. We have the following fundamental definition.

Definition 1 [6]. The *Graver basis* of an integer matrix A is defined to be the finite set $\mathcal{G}(A) \subset \mathbb{Z}^n$ of $\sqsubseteq$ -minimal elements in $\mathcal{L}^*(A) = \{x \in \mathbb{Z}^n : Ax = 0, x \neq 0\}$.

For instance, the Graver basis of the 1×3 matrix $A := [1 \ 2 \ 1]$ consists of 8 elements,

$$\mathcal{G}(A) = \pm \{(2, -1, 0), (0, -1, 2), (1, 0, -1), (1, -1, 1)\}.$$

We now show the fundamental role of the Graver basis of a matrix A in primal methods for linear integer programs of form (1) defined by A . A finite sum $u := \sum_i v_i$ of vectors in $\mathbb{R}^n$ is called *conformal* if all summands lie in the same orthant and hence $v_i \sqsubseteq u$ for all i . It is not hard to see that every $x \in \mathcal{L}^*(A)$ is a conformal sum $x = \sum_i g_i$ of Graver basis elements $g_i \in \mathcal{G}(A)$. This implies the following lemma.

Lemma 1. *A feasible point x in the linear integer program defined by matrix A ,*

$$\min \{wx : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\},$$

is optimal if and only if there is no $g \in \mathcal{G}(A)$ such that $x + g$ is feasible and better.

Proof. One direction is obvious. Suppose then x is not optimal. Let x^* be any better feasible point and put $h := x^* - x$. Then $Ah = b - b = 0$ so $h \in \mathcal{L}^*(A)$ and hence is a conformal sum $h = \sum_i g_i$ with $g_i \in \mathcal{G}(A)$ for all i . Now, $l \leq x, x + h = x^* \leq u$ and $g_i \sqsubseteq h$ imply that $l \leq x + g_i \leq u$ for all i . Also, $A(x + g_i) = Ax = b$ for all i . Therefore, $x + g_i$ is feasible for all i . Now $\sum_i wg_i = wh = wx^* - wx < 0$ implies that $wg_i < 0$ for some g_i in this sum. Therefore, $x + g_i$ is feasible and better.

A primal method for solving Equation (1) or (2) is one that starts from some

feasible point x^0 and generates a sequence $x^0, x^1, x^2, \dots$ of better and better feasible points, namely,

$$\begin{aligned} x^k &\in \mathbb{Z}^n, \quad Ax^k = b, \quad l \leq x^k \leq u, \\ f(x^{k+1}) &< f(x^k), \quad k = 0, 1, 2, \dots \end{aligned} \quad (3)$$

Lemma 1 implies that the Graver basis $\mathcal{G}(A)$ along with an initial feasible point x^0 enables to implement a primal method for problem (1) as follows: given a feasible point x^k in the sequence (3) do: if $wg < 0$ for some $g \in \mathcal{G}(A)$ with $l \leq x^k + g \leq u$ then append the new better feasible point $x^{k+1} := x^k + g$ to the sequence and repeat; otherwise, x^k is optimal. However, this simple implementation does not lead to a polynomial time solution, and a more sophisticated use of the Graver basis is needed.

We proceed to show that the Graver basis *does* enable primal methods for solving linear and various nonlinear integer programming problems in polynomial time.

Separable Convex Objective Functions

We begin with separable convex minimization. So we consider programs of the form

$$\min \{f(x) : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\},$$

where $f : \mathbb{Z}^n \rightarrow \mathbb{Z}$ is a *separable convex* function, that is, $f(x) = \sum_{j=1}^n f_j(x_j)$ with $f_j : \mathbb{Z} \rightarrow \mathbb{Z}$ a univariate convex function for all j . We denote by $\hat{f}$ the maximum value of $|f(x)|$ over the feasible set (which need not be part of the input).

We now show that the Graver basis enables efficient separable convex minimization given an initial feasible point. We later show how to find an initial point as well. Here, we only outline the proof. Complete details can be found in Refs 11 and 12.

Lemma 2. *There is an algorithm that, given an integer $m \times n$ matrix A , its Graver basis $\mathcal{G}(A)$, vectors $l, u \in \mathbb{Z}_\infty^n$ and $x \in \mathbb{Z}^n$ with $l \leq x \leq u$, and separable convex function $f : \mathbb{Z}^n \rightarrow \mathbb{Z}$ presented by a comparison oracle, solves the integer program*

$$\begin{aligned} \min \{f(z) : z \in \mathbb{Z}^n, Az = b, l \leq z \leq u\}, \\ b := Ax, \end{aligned} \quad (4)$$

in time polynomial in the binary-encoding length $\langle A, \mathcal{G}(A), l, u, x, \hat{f} \rangle$ of the data.

Proof. Using linear programming, in polynomial time, either detect that the feasible set is infinite and stop, or conclude that it is finite and continue. Next, produce a sequence of feasible points $x_0, x_1, \dots, x_s$ with $x_0 := x$ the given input point, as follows. Having obtained x_k , solve the minimization problem

$$\min \{ f(x_k + \lambda g) : \lambda \in \mathbb{Z}_+, g \in \mathcal{G}(A), l \leq x_k + \lambda g \leq u \} \quad (5)$$

by minimizing, for each $g \in \mathcal{G}(A)$, the convex univariate function in the integer variable λ using repeated bisections over the relevant interval. If the minimal value in Equation (5) satisfies $f(x_k + \lambda g) < f(x_k)$ then set $x_{k+1} := x_k + \lambda g$ and repeat, else stop and output the last point x_s in the sequence. Now, $Ax_{k+1} = A(x_k + \lambda g) = Ax_k = b$ by induction on k , so each x_k is feasible. Since the feasible set is finite and the x_k have decreasing objective values and hence distinct, the algorithm terminates.

We now show that the point x_s output by the algorithm is optimal. Let x^* be any optimal solution to Equation (4). Consider any point x_k in the sequence and suppose it is not optimal. We claim that a new point x_{k+1} will be produced and will satisfy

$$f(x_{k+1}) - f(x^*) \leq \frac{2n-3}{2n-2} (f(x_k) - f(x^*)) \quad (6)$$

By the integer Carathéodory's theorem [13,14], we can write the difference $x^* - x_k = \sum_{i=1}^t \lambda_i g_i$ as conformational sum involving $1 \leq t \leq 2n-2$ elements $g_i \in \mathcal{G}(A)$ with all $\lambda_i \in \mathbb{Z}_+$. By the supermodularity of separable convex functions [15,16],

$$\begin{aligned} f(x^*) - f(x_k) &= f\left(x_k + \sum_{i=1}^t \lambda_i g_i\right) - f(x_k) \\ &\geq \sum_{i=1}^t (f(x_k + \lambda_i g_i) - f(x_k)). \end{aligned}$$

Suitable manipulation now implies that for some $1 \leq i \leq t$, we have

$$\begin{aligned} f(x_k + \lambda_i g_i) - f(x^*) &\leq \frac{t-1}{t} (f(x_k) - f(x^*)) \\ &\leq \frac{2n-3}{2n-2} (f(x_k) - f(x^*)). \end{aligned}$$

So the point $x_k + \lambda g$ attaining minimum in Equation (5) satisfies

$$\begin{aligned} f(x_k + \lambda g) - f(x^*) &\leq f(x_k + \lambda_i g_i) - f(x^*) \\ &\leq \frac{2n-3}{2n-2} (f(x_k) - f(x^*)) \end{aligned}$$

and so indeed $x_{k+1} := x_k + \lambda g$ will be produced and will satisfy Equation (6). This shows that the last point x_s produced and output by the algorithm is indeed optimal.

We proceed to bound the number s of points. Consider any point $i < s$ and the intermediate nonoptimal point x_i in the sequence produced by the algorithm. Then $f(x_i) > f(x^*)$ with both values being integers, and so repeated use of Equation (6) gives

$$\begin{aligned} 1 &\leq f(x_i) - f(x^*) \\ &= \prod_{k=0}^{i-1} \frac{f(x_{k+1}) - f(x^*)}{f(x_k) - f(x^*)} (f(x) - f(x^*)) \\ &\leq \left(\frac{2n-3}{2n-2} \right)^i (f(x) - f(x^*)) \end{aligned}$$

from which it follows that the number of points s produced by the algorithm satisfies

$$s = O(n \log(f(x) - f(x^*))).$$

Thus, the number of points produced and the total running time are polynomial.

Next, we show that Lemma 2 can also be used to find an initial feasible point for the given integer program or assert that none exists in polynomial time.

Lemma 3. *There is an algorithm that, given integer $m \times n$ matrix A , its Graver basis $\mathcal{G}(A)$,*

$l, u \in \mathbb{Z}_\infty^n$, and $b \in \mathbb{Z}^m$, in time which is polynomial in $\langle A, \mathcal{G}(A), l, u, b \rangle$, either finds a feasible point $x \in S$ or asserts that S is empty or infinite, where

$$S := \{z \in \mathbb{Z}^n : Az = b, l \leq z \leq u\}.$$

Proof. For simplicity, assume that $l, u \in \mathbb{Z}^n$ are finite. For the general case, see Refs 11 or 12. We also may assume $l \leq u$. Now, either detect that there is no integer solution to the system of equations $Ax = b$ (without the lower and upper bound constraints) and stop, or determine such solution $\hat{x} \in \mathbb{Z}^n$ and continue; it is well known that this can be done in polynomial time, say, using the Hermite normal form of A [1]. Next, define a separable convex function on $\mathbb{Z}^n$ by $f(x) := \sum_{j=1}^n f_j(x_j)$ with

$$f_j(x_j) := \begin{cases} l_j - x_j, & \text{if } x_j < l_j \\ 0, & \text{if } l_j \leq x_j \leq u_j \\ x_j - u_j, & \text{if } x_j > u_j \end{cases}, \quad j = 1, \dots, n$$

and extended lower and upper bounds

$$\hat{l}_j := \min\{l_j, \hat{x}_j\}, \quad \hat{u}_j := \max\{u_j, \hat{x}_j\}, \quad j = 1, \dots, n.$$

Consider the auxiliary separable convex integer program

$$\min\{f(z) : z \in \mathbb{Z}^n, Az = b, \hat{l} \leq z \leq \hat{u}\}. \quad (7)$$

Apply the algorithm of Lemma 2 to Equation (7) and obtain, in polynomial time, an optimal solution x . Now note that every point $z \in S$ is feasible in Equation (7), and every point z feasible in Equation (7), satisfies $f(z) \geq 0$ with equality if and only if $z \in S$. So, if $f(x) > 0$ then the original set S is empty, whereas if $f(x) = 0$ then $x \in S$ is a feasible point.

Lemmas 2 and 3 combined together give at once the following theorem showing that the Graver basis enables separable convex minimization in polynomial time.

Theorem 1 [9]. *There is an algorithm that, given integer $m \times n$ matrix A , its*

Graver basis $\mathcal{G}(A)$, $l, u \in \mathbb{Z}_\infty^n$, $b \in \mathbb{Z}^m$, and separable convex $f : \mathbb{Z}^n \rightarrow \mathbb{Z}$ presented by comparison oracle, solves in time polynomial in $\langle A, \mathcal{G}(A), l, u, b, \hat{f} \rangle$ the problem

$$\min\{f(x) : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\}.$$

Ramifications

Linear Integer Programming. Any linear function $wx = \sum_{i=1}^n w_i x_i$ is separable convex. Moreover, an upper bound on $|wx|$ over the feasible set (when finite), which is polynomial in the binary-encoding length of the data, readily follows from Cramer's rule. Therefore we obtain, as an immediate special case of Theorem 1, the following important result, asserting that Graver bases enable the polynomial time solution of linear integer programming.

Theorem 2 [7]. *There is an algorithm that, given an integer $m \times n$ matrix A , its Graver basis $\mathcal{G}(A)$, $l, u \in \mathbb{Z}_\infty^n$, $b \in \mathbb{Z}^m$, and $w \in \mathbb{Z}^n$, solves in time which is polynomial in $\langle A, \mathcal{G}(A), l, u, b, w \rangle$, the following linear integer programming problem,*

$$\min\{wx : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\}.$$

Distance Minimization. Another useful special case of Theorem 1, which is natural in various applications such as image processing, tomography, communication, and error correcting codes, is the following result, which asserts that the Graver basis enables to determine a feasible point which is l_p -closest to a given desired goal point in polynomial time.

Theorem 3 [9]. *There is an algorithm that, given integer $m \times n$ matrix A , its Graver basis $\mathcal{G}(A)$, positive integer p , vectors $l, u \in \mathbb{Z}_\infty^n$, $b \in \mathbb{Z}^m$, and $\hat{x} \in \mathbb{Z}^n$, solves in time polynomial in p and $\langle A, \mathcal{G}(A), l, u, b, \hat{x} \rangle$, the distance minimization problem*

$$\min\{\|x - \hat{x}\|_p : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\}. \quad (8)$$

For $p = \infty$ the problem (8) can be solved in time polynomial in $\langle A, \mathcal{G}(A), l, u, b, \hat{x} \rangle$.

Convex Maximization. We proceed to discuss the *maximization* of a convex function of the composite form $f(Wx)$, with $f: \mathbb{Z}^d \rightarrow \mathbb{Z}$ any convex function and W any integer $d \times n$ matrix.

A *direction* of an edge (1-dimensional face) e of a polyhedron P is any nonzero scalar multiple of $u - v$, where u, v are any two distinct points in e . A result of Ref. 17 asserts, roughly, that if we can optimize in polynomial time linear functions over a set $S \subseteq \mathbb{Z}^n$ and we are given a set $E \subseteq \mathbb{Z}^n$ containing a direction of each edge of the polyhedron $\text{conv}(S)$, then we can also maximize over S convex functions of the above composite form $f(Wx)$ in polynomial time. Nicely enough, it turns out that the Graver basis of a matrix A contains a direction of each edge of $\text{conv}(S)$ with

$$S := \{z \in \mathbb{Z}^n : Az = b, l \leq z \leq u\}.$$

Thus, the result of Ref. 17 together with Theorem 2 imply the following theorem.

Theorem 4 [8]. *For every fixed d , there is an algorithm that, given integer $m \times n$ matrix A , its Graver basis $\mathcal{G}(A)$, $l, u \in \mathbb{Z}_\infty^n$, $b \in \mathbb{Z}^m$, integer $d \times n$ matrix W , and convex function $f: \mathbb{Z}^d \rightarrow \mathbb{R}$ presented by a comparison oracle, solves in time which is polynomial in $\langle A, W, \mathcal{G}(A), l, u, b \rangle$, the convex integer maximization problem*

$$\max \{f(Wx) : x \in \mathbb{Z}^n, Ax = b, l \leq x \leq u\}.$$

N-FOLD INTEGER PROGRAMMING

We now discuss a broad fundamental class of integer programming problems, for which the Graver basis itself can be computed in polynomial time, and hence the Graver based primal methods of the section titled “Graver Based Primal Integer Programming,” lead to polynomial time algorithms.

An $(r, s) \times t$ *bimatrix* is a matrix A consisting of two blocks A_1, A_2 , with A_1 its $r \times t$ submatrix consisting of the first r rows and A_2 its $s \times t$ submatrix consisting of the last s

rows. The n -fold product of A is the following $(r + ns) \times nt$ matrix,

$$A^{(n)} := \begin{pmatrix} A_1 & A_1 & \cdots & A_1 \\ A_2 & 0 & \cdots & 0 \\ 0 & A_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & A_2 \end{pmatrix}.$$

An n -fold integer programming problem is one of the form

$$\min \left\{ f(x) : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u \right\}, \quad (9)$$

that is, with defining matrix which is the n -fold product $A^{(n)}$ of a fixed bimatrix A , and (possibly nonlinear) objective function f . Note that the dimension of an n -fold integer program is nt and is *variable*. Also, n -fold products $A^{(n)}$ are typically not totally unimodular: the n -fold product of the simple $(0, 1) \times 1$ bimatrix with A_1 empty and $A_2 := 2$ satisfies $A^{(n)} = 2I_n$ and has exponential determinant 2^n . So this class of programs cannot be solved by methods of fixed dimension or totally unimodular matrices. The class of n -fold integer programs turns out very natural and has numerous applications. In fact it is *universal*, a result of Ref. 18 implies that every integer program is an n -fold program over the $(3m, 3 + m) \times 3m$ bimatrix A with $A_1 = I_{3m}$ and A_2 the incidence matrix of the bipartite graph $K_{3,m}$ for some m .

It is useful to index each feasible point in Equation (9) as a tuple $x = (x^1, \dots, x^n)$ of n bricks $x^k \in \mathbb{Z}^t$. It turns out [19,20] that for every integer bimatrix A , there is a nonnegative integer $g(A)$, termed the *Graver complexity* of A , such that, for every n , every $x \in \mathcal{G}(A^{(n)})$ in the Graver basis of the n -fold product has at most $g(A)$ nonzero bricks regardless of n . This can be exploited to obtain the following result.

Theorem 5 [7]. *For every fixed integer bimatrix A , there is an algorithm that, given n , computes the Graver basis $\mathcal{G}(A^{(n)})$ in time which is polynomial in n .*

Theorem 5 and the general results on primal integer programming via Graver bases

from the section titled “Graver Based Primal Integer Programming,” along with some further extensions, lead to a sequence of results providing polynomial time solvability of n -fold integer programming with various classes of objective functions, collected in the following theorem. The functions f, g involved are presented by either comparison oracles or evaluation oracles. Also, $\hat{f}, \hat{g}$ denote the maximum values of $|f(Wx)|, |g(x)|$ over the feasible set.

Theorem 6. *For every fixed integer $(r, s) \times t$ bimatrix A , there are algorithms that, given $n, l, u \in \mathbb{Z}_{\infty}^{nt}$, and $b \in \mathbb{Z}^{r+ns}$, solve the following n -fold integer programs:*

1. *Linear Integer Programming [7]. In time polynomial in n and $\langle l, u, b, w \rangle$,*

$$\min\{wx : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u\},$$

with $w \in \mathbb{Z}^{nt}$ any given cost vector.

2. *Convex Maximization [8]. In time polynomial in n and $\langle W, l, u, b \rangle$,*

$$\max\{f(Wx) : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u\},$$

with d fixed, W any given integer $d \times nt$ matrix, and $f : \mathbb{Z}^d \rightarrow \mathbb{R}$ any given convex function presented by a comparison oracle.

3. *Separable Convex Minimization [9].*

$$\min\{f(x) : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u\},$$

with $f : \mathbb{Z}^{nt} \rightarrow \mathbb{Z}$ separable convex function presented by a comparison oracle, in time polynomial in n and $\langle l, u, b, \hat{f} \rangle$.

4. *Distance Minimization [9]. In time polynomial in n, p , and $\langle l, u, b, \hat{x} \rangle$,*

$$\min\{\|x - \hat{x}\|_p : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, l \leq x \leq u\},$$

with p any given positive integer and $\hat{x} \in \mathbb{Z}^{nt}$ any given integer goal point. For $p = \infty$, the problem can be solved in time polynomial in n and $\langle l, u, b, \hat{x} \rangle$.

5. *Weighted Separable Convex Minimization [21].*

$$\min\{f(W^{(n)}x) + g(x) : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, \hat{l} \leq W^{(n)}x \leq \hat{u}, l \leq x \leq u\},$$

with W a fixed integer $(p, q) \times t$ bimatrix, $\hat{l}, \hat{u} \in \mathbb{Z}_{\infty}^{p+nq}$ any given additional bounds, and $f : \mathbb{Z}^{p+nq} \rightarrow \mathbb{Z}, g : \mathbb{Z}^{nt} \rightarrow \mathbb{Z}$ any given separable convex functions presented by evaluation oracles, in time polynomial in n and $\langle l, u, \hat{l}, \hat{u}, b, \hat{f}, \hat{g} \rangle$.

SOME APPLICATIONS

We now demonstrate the power of Graver bases and n -fold integer programming, and describe important applications for transportation and multicommodity flow.

The Multi-Index Transportation Problem.

Problems involving multiply-indexed variables have been studied extensively in mathematical programming in the context of multi-index dimensional transportation (see Refs 22 and 23 and references therein) and in statistics in the context of disclosure control and privacy in statistical databases (see Refs 24 and 25 and references therein). Theorem 6 leads to the first polynomial time algorithms for a variety of problems in these two contexts. Here, we discuss only applications to triple-index transportation problems. Discussion of further applications can be found in Refs 11 and 12.

The multi-index transportation problem was introduced by Motzkin in Ref. 26. For simplicity, we discuss here only the triple-index problem with specified line-sums,

$$\min\left\{wx : x \in \mathbb{Z}_+^{l \times m \times n}, \sum_i x_{i,j,k} = v_{*,j,k}, \sum_j x_{i,j,k} = v_{i,*,k}, \sum_k x_{i,j,k} = v_{i,j,*}\right\}, \quad (10)$$

where the specified line-sums are $mn + ln + lm$ given nonnegative integer numbers

$$v_{*,j,k}, v_{i,*,k}, v_{i,j,*}, \quad 1 \leq i \leq l, 1 \leq j \leq m, 1 \leq k \leq n.$$

If l, m, n are all fixed then the problem is solvable in polynomial time using integer programming in fixed dimension lmn [3]. If l, m, n are all variables then the problem is NP-hard [27]. The in-between cases are much more delicate and were resolved only recently. If two sides are variable and one is fixed then the problem is still NP-hard [28]. In fact, the recent universality theorem of Ref. 18 implies that *every* integer program is a $3 \times m \times n$ transportation problem for some m and n . We now show that if two sides are fixed and one is variable, then the problem can be solved in polynomial time by the Graver based primal algorithms. Note that even over $3 \times 3 \times n$ tables, the only solution of the problem available to-date is the one given below.

Theorem 7 [7]. *For every fixed l and m , there is an algorithm that, given n , integer $l \times m \times n$ cost w , and integer line-sums $v = (v_{*,j,k}, v_{i,*,k}, v_{i,j,*})$, solves Motzkin's triple-index transportation problem (10) in time which is polynomial in n and $\langle w, v \rangle$.*

Proof. Reindex arrays as $x = (x^1, \dots, x^n)$ with each $x^k = (x_{i,j,k})$ a suitably indexed lm vector representing the k th layer of x . Similarly reindex w . Let $t := r := lm$ and $s := (l + m)$. Let $b := (b^0, b^1, \dots, b^n) \in \mathbb{Z}^{r+ns}$, where $b^0 := (v_{i,j,*})$ and

$$b^k := ((v_{*,j,k}), (v_{i,*,k})), \quad k = 1, \dots, n.$$

Let A be the $(t, s) \times t$ bimatix with first block $A_1 := I_t$ the $t \times t$ identity matrix and second block A_2 a matrix defining the line-sum equations on $l \times m$ arrays. Then the equations $A_1(\sum_{k=1}^n x^k) = b^0$ are the line-sum equations $\sum_{k=1}^n x_{i,j,k} = v_{i,j,*}$ where summations over layers occur, whereas the equations $A_2 x^k = b^k$ for $k = 1, \dots, n$ represent all other line-sum equations, where summations are within a single layer at a time. So the transportation problem is encoded as the n -fold program

$$\min \{wx : x \in \mathbb{Z}^{nt}, A^{(n)}x = b, x \geq 0\}.$$

By Theorem 6 part 1, this n -fold integer program, and hence the given multi-index

transportation problem, can be solved in polynomial time.

This proof can be extended to multi-index transportation problems of higher dimension $m_1 \times \dots \times m_d \times n$, to any margin constraints, and to nonlinear objective functions of the forms appearing in the various parts of Theorem 6 [12].

The Multicommodity Transportation Problem. The *multicommodity transportation* problem seeks minimum cost routing of several discrete commodities from m suppliers to n consumers subject to supply, demand, and capacity constraints. The problem data is as follows. There are l types of commodities with $v_k \in \mathbb{Z}_+$ the volume per unit flow of commodity k . Each supplier i has a supply vector $s^i \in \mathbb{Z}_+^l$ with s_k^i its supply in commodity k , and each consumer j has a consumption vector $c^j \in \mathbb{Z}_+^l$ with c_k^j its consumption in commodity k . A multicommodity transportation is a vector $x = (x^1, \dots, x^n)$ with $x^j = (x_{1,1}^j, \dots, x_{1,l}^j, \dots, x_{m,1}^j, \dots, x_{m,l}^j)$, where $x_{i,k}^j$ is the flow of commodity k from supplier i to consumer j . The capacity constraint on channel (i, j) is $\sum_{k=1}^l v_k x_{i,k}^j \leq u_{i,j}$. The cost of transportation x is defined as follows. There are cost functions $f_{i,j} : \mathbb{Z} \rightarrow \mathbb{Z}$ for each channel and $g_{i,k}^j : \mathbb{Z} \rightarrow \mathbb{Z}$ for each channel and commodity. The transportation cost on channel (i, j) is $f_{i,j}(\sum_{k=1}^l v_k x_{i,k}^j) + \sum_{k=1}^l g_{i,k}^j(x_{i,k}^j)$ with the first term being the value of $f_{i,j}$ on the combined volume of flow of all commodities on channel (i, j) , and the second term being the sum of costs that depend on both the channel and the commodity. The total cost of transportation x is

$$\sum_{i,j} \left(f_{i,j} \left(\sum_{k=1}^l v_k x_{i,k}^j \right) + \sum_{k=1}^l g_{i,k}^j(x_{i,k}^j) \right).$$

Our results apply to cost functions which can be standard linear or convex such as $\alpha_{i,j} |\sum_{k=1}^l v_k x_{i,k}^j|^{\beta_{i,j}} + \sum_{k=1}^l \gamma_{i,k}^j |x_{i,k}^j|^{\delta_{i,k}^j}$ for some nonnegative integers $\alpha_{i,j}, \beta_{i,j}, \gamma_{i,k}^j, \delta_{i,k}^j$, which take into account the increase in cost due to channel congestion when subject to heavy traffic or communication load (the linear case occurs with $\beta_{i,j} = \delta_{i,k}^j = 1$).

We consider the problem with fixed (but arbitrary) number l of commodities, fixed number m of suppliers, and *variable* number n of consumers. This is very natural in operations research applications, where few facilities serve many customers. (If the number m of suppliers is also variable then the problem is NP-hard already for $l = 2$ commodities.) We point out that even with only $m = 3$ suppliers and $l = 2$ commodities, the only solution available to-date is the one given below.

We have the following theorem on (non-linear) multicommodity transportation. As before, $\hat{f}, \hat{g}$ denote the maximum absolute values of f, g over the feasible set.

Theorem 8 [21]. *For any fixed l commodities, m suppliers, and volumes v_k , there is an algorithm that, given n consumers, supplies and demands $s^i, c^j \in \mathbb{Z}_{+}^l$, capacities $u_{i,j} \in \mathbb{Z}_{+}$, and convex costs $f_{i,j}, g_{i,k}^j : \mathbb{Z} \rightarrow \mathbb{Z}$ presented by evaluation oracles, solves in time polynomial in n and $\langle s^i, c^j, u, \hat{f}, \hat{g} \rangle$, the multicommodity transportation problem,*

$$\begin{aligned} \min \quad & \sum_{i,j} \left(f_{i,j} \left(\sum_{k=1}^l v_k x_{i,k}^j \right) + \sum_{k=1}^l g_{i,k}^j (x_{i,k}^j) \right) \\ \text{s.t.} \quad & x_{i,k}^j \in \mathbb{Z}, \quad \sum_j x_{i,k}^j = s_k^i, \quad \sum_i x_{i,k}^j = c_k^j, \\ & \sum_{k=1}^l v_k x_{i,k}^j \leq u_{i,j}, \quad x_{i,k}^j \geq 0. \end{aligned}$$

Proof. Construct bimatrices A and W as follows: Let D be the $(l, 0) \times l$ bimatrix with first block $D_1 := I_l$ and second block D_2 empty. Let V be the $(0, 1) \times l$ bimatrix with first block V_1 empty and second block $V_2 := (v_1, \dots, v_l)$. Let A be the $(ml, l) \times ml$ bimatrix with first block $A_1 := I_{ml}$ and second block $A_2 := D^{(m)}$. Let W be the $(0, m) \times ml$ bimatrix with first block W_1 empty and second block $W_2 := V^{(m)}$. Let b be the $(ml + nl)$ -vector $b := (s^1, \dots, s^m, c^1, \dots, c^n)$.

Let $f : \mathbb{Z}^{nm} \rightarrow \mathbb{Z}$ and $g : \mathbb{Z}^{nml} \rightarrow \mathbb{Z}$ be the separable convex functions defined by $f(y) := \sum_{i,j} f_{i,j}(y_{i,j})$ with $y_{i,j} := \sum_{k=1}^l v_k x_{i,k}^j$ and $g(x) := \sum_{i,j} \sum_{k=1}^l g_{i,k}^j(x_{i,k}^j)$.

Now note that $A^{(n)}x$ is an $(ml + nl)$ -vector, whose first ml entries are the flows from each supplier of each commodity to all consumers, and whose last nl entries are the flows to each consumer of each commodity from all suppliers. Therefore the supply and consumption equations are encoded by $A^{(n)}x = b$. Next note that the nm -vector $y = (y_{1,1}, \dots, y_{m,1}, \dots, y_{1,n}, \dots, y_{m,n})$ satisfies $y = W^{(n)}x$. So the capacity constraints become $W^{(n)}x \leq u$ and the cost function becomes $f(W^{(n)}x) + g(x)$. Therefore, the problem is precisely the following n -fold integer program,

$$\min \left\{ f(W^{(n)}x) + g(x) : x \in \mathbb{Z}^{nml}, A^{(n)}x = b, W^{(n)}x \leq u, x \geq 0 \right\}.$$

By Theorem 6 part 5, this program can be solved in polynomial time as claimed.

PORTUGUESE OPERATIONAL RESEARCH SOCIETY—APDIO

DOMINGOS M. CARDOSO
Departamento de Matemática,
Universidade de Aveiro,
Aveiro, Portugal

PEDRO OLIVEIRA
Instituto de Ciências Biomédica
Abel Salazar, Universidade
do Porto, Porto, Portugal

MISSION AND ORGANIZATION

The Portuguese Operational Research (OR) Society (in Portuguese: Associação Portuguesa de Investigação Operacional—APDIO) is a scientific society that brings together the Portuguese community interested in OR. APDIO was founded in 1978 by 140 founding members, including university researchers, industrial professionals, and several Portuguese institutes and companies as institutional associates. The list of founding institutional associates included LISNAVE—Shipyard company, PETROGAL—Oil and Gas Company of Portugal, INESC—Institute of Systems Engineering and Computers, Portuguese General Directorate of Hydro-energy, LNETI—National Laboratory of Engineering and Industrial Technology, PROFABRIL—Portuguese Consulting Group, CIFAG—Government Investment Institute, Espírito Santo e Comercial Bank of Lisbon, CESUR—Center for Urban and Regional Systems, CTT—Post and Telecommunications of Portugal, CAUTL—Center of Automation of the Technical University of Lisbon, INA—National Institute for Public Administration, Direcção Geral de Energia—Portuguese General Directorate for Energy Policy, and PARTEX—Oil and Gas Corporation.

The main objective of the APDIO is to disseminate the most recent advances in OR

and its best practices and, furthermore, to strengthen the links between the OR community members on the basis of their research interests and challenges.

The APDIO defines its mission as contributing to the advance of OR through courses, seminars, workshops, conferences, and publications (such as scientific journals, bulletins, and books). Furthermore, the APDIO promotes the exchange of results, experiences, and OR applications by electronic means such as its web page ([//apdio.pt/home](http://apdio.pt/home)).

The APDIO is composed of a General Assembly (which is directed by a president and two secretaries and includes all its members), a Directive Committee (composed of a president, four vice presidents, a treasurer, and a secretary), and an Accounting Committee (composed of a president, a rapporteur, and a secretary). Each of these committees is elected for a period of two years. The General Assembly and the Accounting Committee meet regularly once a year, and the Directive Committee meets every two months. At present, the APDIO has about 300 associate members, and it is hosted (since its beginning) at CESUR—IST, Technical University of Lisbon (E-mail: apdio@civil.ist.utl.pt).

THE APDIO ACTIVITIES

The Portuguese OR Society is a member of the International Federation of Operational Research Societies (IFORS) and the International Federation of Automatic Control IFAC since its very beginning. Later, it became a member of the Association of European Operational Research Societies (EURO) and was involved in the foundation, in 1982, of the Association of Latin–Iberoamerican Operational Research Societies (ALIO). APDIO has a reciprocity agreement with the Brazilian Society of Operations Research (SOBRAPO) since 2001.

The APDIO has organized 15 national conferences in the following places and years: Lisboa, 1982; Porto, 1984; Coimbra, 1987;

Lisboa, 1989; Évora, 1992; Braga, 1994; Aveiro, 1996; Faro, 1998; Setúbal, 2000; Guimarães, 2002; Porto, 2004; Lisboa, 2006; Vila Real, 2008; Caparica, 2009; and Coimbra, 2011. The next National Conference will be held in Bragança in 2013.

The APDIO has organized and supported about 30 international conferences; among these conferences, we highlight the following:

- EURO VIII—European Conference on Operational Research, Lisbon, September, 1986
- IFORS 93—XIII World Conference on Operations Research, Lisbon, July, 1993
- The Optimization Conferences (Braga, 1995; Coimbra, 1998; Aveiro, 2001; Lisbon, 2004; Porto, 2007; and Lisbon, 2011)
- EURO XXIV—European Conference on Operational Research, Lisbon, July, 2010

The scientific journal of the APDIO, *Investigação Operacional*, was published between 1981 and 2008, totaling 28 volumes.

The editors in chief were Isabel Hall Themido, Technical University of Lisbon, 1981–1983; José Manuel Viegas, Technical University of Lisbon, 1984–1985; José Pinto Paixão, University of Lisbon, 1986–1987; Joaquim João Júdice, University of Coimbra, 1988–2004; and José Fernando Oliveira, University of Porto, 2004–2008.

The newsletter of the APDIO, *Boletim*, was published, twice a year, between 1984 and 2005, and its publication was resumed in 2010. The editors were José Manuel Viegas, Technical University of Lisbon, 1984–1986; António José Rodrigues, University of Lisbon, 1987–1990; Jorge Pinho de Sousa, University of Porto, 1991–1992; Carlos Henggeler Antunes, University of Coimbra, 1993–1999; João Paulo Costa, University of Coimbra, 2000–2002; João Luís Soares, University of Coimbra, 2003–2005; and Ana Camanho and Bernardo Almada Lobo, University of Porto, 2010–2011.

The current editors are Ana Luísa Custódio and Isabel Correia, New University of Lisbon.

Since OR's visibility comes from its applications in industry and services, in 2000, APDIO sponsored the publication of a book about case studies of real-world applied problems of OR in Portugal (in Portuguese), edited by Carlos Henggeler Antunes (University of Coimbra) and Luís Valadares Tavares (Technical University of Lisbon) [1]. Now, another book reporting successful applications of OR, edited by José Soeiro Ferreira (University of Porto) and Rui Carvalho Oliveira (Technical University of Lisbon), is in preparation.

Over the past 30 years, the activities of the Portuguese OR Society were held, mostly through its associates, researchers, and practitioners, who have dedicated much of their effort to promote the OR through the APDIO. We just mention those who had the utmost responsibility, the presidents of the Portuguese OR Society. They were Luís Valadares Tavares, Technical University of Lisbon, 1978–1985; José Dias Coelho, New University of Lisbon, 1986–1989; Rui Campos Guimarães, University of Porto, 1990–1994; Isabel Hall Themido, Technical University of Lisbon, 1995–1996; Luís Valadares Tavares, Technical University of Lisbon, 1997–1998; José Soeiro Ferreira, University of Porto, 1999–2001; José Valério de Carvalho, University of Minho, 2002–2004; Jorge Pinho de Sousa, University of Porto, 2005–2009; and Joaquim João Júdice, University of Coimbra, 2010–2011.

FUTURE CHALLENGES

Future challenges can be summarized in the strengthening of the presence of the OR community in the society at large. The present financial crisis, although with negative direct effects on financing research and higher education institutions, can become an opportunity for the OR community. The pressure to reduce costs at all levels and for a more efficient use of limited resources motivates the OR community to intervene, using its techniques and tools to propose solutions. In particular, the current Directive Committee has defined two major areas of public intervention, energy, and health systems (namely, the problems raised by their high costs and

its impact on the economic and social development of the country).

Most of the APDIO members belong to the Portuguese universities and polytechnic institutes. However, several private institutions and companies are also presented by their OR practitioners and some of them as institutional associates. One of the main goals of the current Directive Committee is to increase the participation of industrial and service sectors in APDIO initiatives and to improve the utilization of OR methodologies in such environments. The one-day meetings “OR in Companies” with the aim of analyzing particular problems by academics and practitioners and sharing their experience will be more frequent and extended to more institutions.

The Portuguese OR Society also considers that its presence in the education system has to be reinforced. In the first place, the APDIO must intervene in the definition of the mathematics curricula of secondary education, so that the curricula can be an introduction to the field of knowledge, which is largely unknown to the general public. With respect to higher education, the APDIO feels that the Bologna reform may have, in some graduations, reduced the presence of OR in the

curricula. Therefore, the teaching of OR has been largely shifted to postgraduate level [2]. In this particular aspect, the APDIO is challenging the different universities, for the development of a PhD program in OR. Research is also of a great concern, in particular, with the expected reduced funds. APDIO, jointly with the different research groups, is pressing the Portuguese National Science Foundation for the creation of a funding area dedicated solely to OR.

Finally, it is worth to mention that we believe in the continuity of the APDIO as an institutional research reference for the OR community in Portugal. The renovation of generations and the new social and economic challenging problems for the development of human societies ensures that OR will be even more visible and more effective in the near future.

POWER INDICES

JOSEP FREIXAS

Department of Applied Mathematics 3
and High Engineering School
(Campus of Manresa), Technical
University of Catalonia, Madrid,
Spain

INTRODUCTION

Roughly speaking, a power index is a numerical measure that estimates the a priori capacity or influence of each voter in a simple game. Of course the notion of power is complex and has been analyzed in depth by several authors. An interesting reference is the subtle book by Morriss [1], which analyzes power under a philosophical point of view.

Simple games form an interesting subclass of transferable utility cooperative games and are frequently used as a test bed for cooperative concepts. In a simple game, the members of a coalition can be seen as those who vote in favor of a certain law, while the others vote against it. The binary output $\{0, 1\}$ in simple games converts them in appropriate models for binary voting systems in which each coalition either becomes winning (output 1) and can force the passage of the bill at hand, or becomes losing (output 0) and cannot force the passage of the bill. It should be noted that the binary output allows the description of the game by only giving the set of winning (or, alternatively, losing) coalitions.

Several power indices found in the literature are, simply, the restriction of a cooperative value to this subclass: for example, the Shapley–Shubik index [2] is the restriction of the well-known Shapley value [3]. The power of a voter as discussed in Ref. 2 can be viewed as his/her *expected share in a fixed total prize*, that is, the power of a voter is meant to be voter's expected payoff. This idea was followed by several scholars (e.g. Deegan and Packel [4], Johnston [5]

and Holler [6], among others) who introduced alternative efficient power indices. All these authors followed the seminal ideas by Dubey [7] and Dubey and Shapley [8], and provided axiomatic characterizations of their indices. Hence, the acceptance of an index as a valid measure of power depends on how we are willing to accept the properties that uniquely characterize it.

Another alternative point of view, far from cooperative game theory, was followed by other scholars, for which a member's voting power is the degree to which that member's vote is able to *influence* the outcome of a division: whether the bill in question will pass or fail. A way to formally explicate this idea is in terms of probabilities. The three authors—Penrose [9], Banzhaf [10], and Coleman [11]—who, independent of each other, offered a mathematical explication of power as influence, adopted a probabilistic approach.

Felsenthal and Machover [12] in collaboration with Zwicker distinguished between these two previous sources of power. However, this distinction is not exclusive since; for example, the Shapley–Shubik index can be derived from the two approaches.

The main assumption when computing power indices is that all relevant information is encapsulated in the game. Hence, power indices can directly be computed from the characteristic function or, equivalently, from its set of winning coalitions. However, there are many other more sophisticated models that require exogenous information, specially concerning the formation of coalitions. Both sources have been extensively treated in the literature.

Simple games have served as theoretical models in many fields far from game theory, in spite of the fact that no rationality needs to be assumed for the “agents” in these fields. Nevertheless, the main application of simple games has always been the analysis of binary voting procedures and hence of political structures. Note, for instance, that the Barlow and Proshan index in reliability

corresponds to the Shapley–Shubik index and the Birnbaum index in reliability corresponds to the Banzhaf index. Here we regard only power indices in the politics context.

This short compendium on power indices is organized as follows. Section titled “Simple Games” recalls the notion of simple game and introduces some subclasses of them mainly based on the completeness of some preorderings. Section titled “Power Indices” provides the definitions of some of the most recognized power indices. Section titled “Properties of Power Indices” lists some reasonable properties for power indices, but disregards many others for lack of space, and explains which of them are satisfied for the power indices introduced. Section titled “Axiomatizations versus Probabilistic Approach” contains a brief probabilistic approach of some indices. Section titled “Discussion” summarizes the occurrence of some desirable properties for power indices and considers their ordinal equivalence. Finally, section titled “Miscellaneous” contains a compendium of significant issues related with power indices that have been developed in the literature.

SIMPLE GAMES

In the sequel, $N = \{1, 2, \dots, n\}$ denotes a fixed but otherwise arbitrary finite set of *players*. Any subset $S \subseteq N$ is a *coalition* and N itself is called the *grand coalition*. A cooperative game v (in N , omitted hereafter) is a *simple game* if (i) $v(S) = 0$ or 1 for all S , (ii) is monotonic, that is, $v(S) \leq v(T)$ whenever $S \subset T$, and (iii) $v(N) = 1$ (if condition (iii) is not required, then $v \equiv 0$ and hence $\mathcal{W} = \emptyset$ is also a simple game, which is convenient when restriction of simple games is considered, see first paragraph of section titled “Coalition Structures”). Either the family of *winning* coalitions $\mathcal{W} = \mathcal{W}(v) = \{S \subseteq N : v(S) = 1\}$ or the subfamily of *minimal* winning coalitions $\mathcal{W}^m = \mathcal{W}^m(v) = \{S \in \mathcal{W} : T \subset S \Rightarrow T \notin \mathcal{W}\}$ determines the game. We denote the set of simple games by S_N on N .

Von Neumann and Morgenstern [13] considered a very restrictive class of simple games. Some authors (Shapley in Ref. 3) extended their class. They consider the

definition above plus the requirement of *properness*: whenever $S \in \mathcal{W}$ and $T \in \mathcal{W}$ then $S \cap T \neq \emptyset$. Improper games rarely occur in politics, but they appear, for example, when the US Supreme Court gives a grant of *certiorari*, which requires approval by four out of the nine justices of court.

For any $\mathcal{W}, \mathcal{V} \in S_N$, we can define two new simple games by the ordinary set operations:

$$\begin{aligned}\mathcal{W} \cap \mathcal{V} &= \{S \in N : S \in \mathcal{W} \text{ and } S \in \mathcal{V}\}, \\ \mathcal{W} \cup \mathcal{V} &= \{S \in N : S \in \mathcal{W} \text{ or } S \in \mathcal{V}\}.\end{aligned}$$

Endowed with these set operations, S_N becomes a distributive lattice.

Power index. Any map $f : S_N \rightarrow \mathbb{R}^n$ with $|N| = n$ is a *power index*. The i th component is interpreted as a measure of the power that the simple game $\mathcal{W}$ confers to i . Any power index f induces a total preordering on the set of voters by $i \succsim_f j \Leftrightarrow f(i) \geq f(j)$. In this case $\succsim_f$ is called the *separability* relation for the power index f .

Crucial voters. This concept is in the ground of the definition of most power indices. We say that player i is *crucial* for a coalition S if $i \in S$ and $S \in \mathcal{W}$ but $S \setminus \{i\} \notin \mathcal{W}$. We will use notations:

$$\begin{aligned}C_i &= \{S \subseteq N : i \text{ is crucial in } S\}, \\ C_i(k) &= \{S \subseteq N : i \text{ is crucial in } S \\ &\quad \text{and } |S| = k\}.\end{aligned}$$

Some Significant Subclasses of Simple Games

There are two important subclasses of simple games that are worth taking into account: complete games (which include the well-known weighted games) and weakly complete games. Both subclasses are characterized by the completeness of a certain preordering on N .

There are at least two purposes of introducing these subclasses. First, practically all real-life binary voting systems are of some of these types and, second, the two preorderings we are going to introduce attempt to formalize the intuitive notion that underlies expressions such as the following: “ i and j have equal power,” “ i has at least as much power as j ,” “ i is preferable to j as a coalitional partner.”

Desirability relation. It was introduced by Isbell [14]. Let $\mathcal{W} \in \mathcal{S}_N$, $i, j \in N$. Define

$$i \succsim_D j \quad \text{iff} \quad S \cup \{j\} \in \mathcal{W} \Rightarrow S \cup \{i\} \in \mathcal{W} \\ \text{for all } S \subseteq N \setminus \{i, j\}.$$
